Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on their own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assume any liability for any injury and/or damage to persons or property arising out or related to any use of the material contained in this book.

Preface to the Third Edition

A period of 15 years elapsed between the appearance of the first and second editions of our textbook. We have produced the third edition in just over a half of this time, but much has happened in the interim. The task of putting together this new edition has proved just as hard as was that of producing the second edition. Apart from one of us, all of the initial editors have now stepped down from the editorial team. Sadly, one of our number, Fergus Macartney, is no longer with us. The new editors take this opportunity to acknowledge his role in getting the first edition off the ground. We also express a huge debt of gratitude to Elliot Shinebourne and Mike Tynan, who are now enjoying richly deserved and fruitful retirements. Our remaining initial editor is also allegedly retired, but still in harness with new appointments at the Medical University of South Carolina and Newcastle University.

As already indicated, much has happened in the field of cardiac disease in the young since the turn of the millennium. All of these changes are reflected in this third edition, which is markedly changed from our second offering. One of the major changes is the geographic representation of the editorial team, with editorial input now provided from Europe, North America and Australasia. To further offer a worldwide perspective, we have invited authors from five continents to contribute their cutting-edge expertise to the new edition.

Readers will note multiple changes in the format of the book, thanks to the suggestions of our publisher. Thankfully, we are now able to include color illustrations throughout the book. The influence of this change on the figures is truly spectacular. Also, the third edition now includes access to the full content of the book via a dedicated Expert Consult website. We have chosen to include the full lists of references exclusively in this web version, closing each of the chapters in the print version with a list of annotated references. In this way, we have been able to condense the contents into a single volume, which we consider a significant advance.

Although we have made these multiple changes, we hope that the overall philosophy and approach of the book is unchanged. As with the previous edition, we have sought to maintain a standard style throughout the text. We hope that the uniformity achieved, along with an avoidance of abbreviations, will make the text appreciably easier to read and assimilate. Some of the revised chapters took some time to be written, but the quality of the chapters made the wait worthwhile. It is our belief that we have produced a truly first-class third edition.

We thank all our contributing authors for their efforts in making this possible. We also thank the editorial and production teams at Elsevier for smoothing the path towards publication, in particular Pamela Hetherington, who laboured beyond the call of duty in her efforts to obtain all the chapters on time. We are also indebted to Linnea Hermanson, production editor, who made correction of the proofs a pleasurable task rather than a chore. We particularly wish to thank Gemma Price, who drew and coloured the majority of the beautiful cartoons that grace our pages. We also express our thanks to our various friends and colleagues who permitted us to use illustrations from various previous collaborative ventures. We have cited their contributions in the legends to the specific figures, hoping that we have not made any omissions. We close this preface to the third edition with the same hopes as expressed for the second edition. It is our belief that this version marks a significant step upwards in the quality of our textbook. We hope that you, the reader, share our own enthusiasm as you make your way through its pages.

Terminology

ROBERT H. ANDERSON

It might reasonably be thought that those who diagnose and treat patients with congenitally malformed hearts would, by now, have reached consensus concerning the most appropriate way of describing the malformations with which they are confronted. It is certainly the case that nomenclature is far less contentious now than when we produced the first two editions of this book, in 1987 and 1999. It would be a brave person, nonetheless, who stated that the field of description and categorisation was now fully resolved. There are still major differences of opinion as how best to cope with certain topics, such as those patients who have visceral heterotaxy (or so-called splenic syndromes). It is not our intention, in this chapter, to initiate detailed debates on the differences in the approaches to these, and other, contentious issues. Rather, we will describe our own system for description, leaving the readers to decide whether or not this is satisfactory for their needs. By and large, there is no right or wrong way of describing the hearts, simply different ways.^{1,2} Even these different ways have been mitigated to considerable extent by the cross-mapping of existing systems,³ but this should not detract from the need to resolve ongoing differences according to the nature of the abnormal anatomy as it is observed.

It may be asked, however, whether we need a system for nomenclature, since the hearts themselves have not changed since their initial descriptions. The reason that a standardised approach is preferable is that the number of individual lesions that can co-exist within malformed hearts is considerable. Add to this the possibilities for combinations of lesions, and the problem of providing pigeon-holes for each entity becomes immense. We all recognise the nature of straightforward lesions, such as septal deficiencies or valvar stenoses. Almost always these entities are encountered in otherwise normally structured hearts. It is when the hearts containing the lesions are themselves built in grossly abnormal fashion that difficulties are produced. We can no longer be satisfied with a wastebasket category for so-called complex lesions. The recognition of apparent complexity does nothing to determine diagnosis or optimal treatment. If these alleged complex lesions are approached in a simple and straightforward fashion, none need be difficult to understand and describe.

The simplicity comes when we recognise that, basically, the heart has three building blocks, namely the atriums, the ventricular mass and the arterial trunks (Fig. 1-1). A system for description and categorisation based on recognition of the limited potential for variation in each of these cardiac segments was developed independently in the 1960s by two groups: one based in the United States of America, and led by Richard Van Praagh,¹ and the other, from Mexico City,

headed by Maria Victoria de la Cruz.⁴ Both of these systems concentrated on the different topological arrangements of the components within each cardiac segment. When Van Praagh and his colleagues^{5,6} introduced the concept of concordance and discordance between atriums and ventricles, they were concerned primarily with the harmony or disharmony to be found between atrial and ventricular situs. At this time, they placed less emphasis for description on the fashion in which the atrial and ventricular chambers were joined together across the atrioventricular junctions. A similar approach, concentrating on arterial relationships, was taken by de la Cruz and colleagues⁷ when they formulated their concept of arterio-ventricular concordance and discordance. These approaches were understandable, since it was often difficult, at that time, precisely to determine how the adjacent structures were linked together.

The advent of cross sectional echocardiography changed all that. Since the mid-1970s, it has been possible with precision to determine how atriums are, or are not, joined to ventricles, and similarly to establish the precise morphology found at the ventriculo-arterial junctions. Since we evolved our system concomitantly with the development of echocardiography, our approach has been to concentrate on the variations possible across the atrioventricular and ventriculo-arterial junctions. We call this system sequential segmental analysis (see Fig. 1-1). In making such analysis, we do not ignore the segments themselves. Indeed, junctional

Figure 1-1 The cartoon shows the essence of sequential segmental analysis. It depends on recognition of the topological arrangement of the three cardiac segments, and combines this with analysis of the fashions in which the segments are joined or are not joined to each other.

connections cannot be established without knowledge of segmental topology. In this respect, we have acknowledged our debts to the other schools as our system has evolved.⁸⁻¹²

Our system, throughout its evolution, has followed the same basic and simple rules. From the outset, we have formulated our categories on the basis of recognisable anatomical facts, avoiding any speculative embryological assumptions. Again, from the start, we have emphasised the features of the morphology of the cardiac components, the way they are joined or not joined together, and the relations between them, as three different facets of the cardiac make-up. It still remains an undisputed fact that any system which separates out these features, does not use one to determine another, and describes them with mutually exclusive terms, must perforce be unambiguous. The clarity of the system then depends upon its design. Some argue that brevity is an important feature and have constructed formidable codifications to achieve this aim.¹³ In the final analysis, however, clarity is more important than brevity. We do not shy, therefore, from using words to replace symbols, even if this requires several words. Whenever possible, we strive to use words that are as meaningful in their systematic role as in their everyday usage. In our desire to achieve optimal clarity, we have made changes in our descriptions over the years, most notably in our use of the term univentricular heart. We make no apologies for these changes, since their formulation, in response to valid criticisms, has eradicated initially illogical points from our system to its advantage. It is our belief that the system now advocated is entirely logical, and we hope it is simple. But, should further illogicalities become apparent, we would extirpate them as completely as we removed¹⁴ univentricular heart from our lexicon as an appropriate descriptor for hearts that possess one big and one small ventricle, showing that this can produce a functionally, but not anatomically, univentricular arrangement.¹⁵

BASIC CONCEPTS OF SEQUENTIAL SEGMENTAL ANALYSIS

The system we advocate depends first upon the establishment of the arrangement of the atrial chambers. Thereafter, attention is concentrated on the anatomical nature of the junctions between the atrial myocardium and the ventricular myocardial mass. This feature, which we describe as a type of connection, is separate from the additional feature of the morphology of the valve or valves that guards the junctions. There are two junctions in the normally constructed heart, and usually they are guarded by two separate valves. The two atrioventricular junctions can be guarded, on occasion, by a common valve. If we are to achieve this analysis of the atrioventricular junctions, we must also determine the structure, topology, and relationships of the chambers within the ventricular mass. As with the atrioventricular junctions, the ventriculo-arterial junctions are also analysed in terms of the way the arterial trunks are joined to the ventricular mass, and the morphology of the arterial valves guarding their junctions. Separate attention is directed to the morphology of the outflow tracts, and to the relationships of the arterial trunks. A catalogue is then made of all associated cardiac and, where pertinent, non-cardiac malformations. Included in this final category are such features as the location of the heart, the orientation

of its apex, and the arrangement of the other thoracic and abdominal organs.

Implicit in the system is the ability to distinguish the morphology of the individual atriums and ventricles, and to recognise the types of arterial trunk taking origin from the ventricles. This is not as straightforward as it may seem, since often, in congenitally malformed hearts, these chambers or arterial trunks may lack some of the morphological features that most obviously characterise them in the normal heart. The most obvious feature of the morphologically left atrium in the normal heart, for example, is the connection to it of the pulmonary veins. In hearts with totally anomalous pulmonary venous connection, these veins connect in extracardiac fashion. In spite of this, it is still possible to identify the left atrium. It is considerations of this type that prompted the concept we use for recognition of the cardiac chambers and great arteries. Dubbed by Van Praagh and his colleagues the morphological method,¹⁶ and based on the initial work of Lev,¹⁷ the principle states that structures should be recognised in terms of their own intrinsic morphology, and that one part of the heart which is itself variable should not be defined on the basis of another variable structure. When this eminently sensible concept is applied to the atrial chambers, then the connections of the great veins are obviously disqualified as markers of morphological rightness or leftness since, as discussed above, the veins do not always connect to their anticipated atriums. Although Lev¹⁷ placed great stress on septal morphology as a distinguishing feature, this morphology is of little help when the septum itself is absent, as occurs in hearts with a common atrium. Similarly, the atrial vestibule is ruled out as a marker, since it is usually lacking in hearts with atrioventricular valvar atresia. Fortunately, there is another component of the atrial chambers that, in our experience, has been almost universally present and which, on the basis of the morphology of its junction with the remainder of the chambers, has enabled us always to distinguish between morphologically right and left atriums. This is the appendage. The morphologically right appendage has the shape of a blunt triangle, and its cavity has a broad junction with the remainder of the atrium. The junction is marked externally by the terminal groove, and internally by the terminal crest. Its most significant feature is that the pectinate muscles lining the appendage extend all round the parietal atrioventricular junction (Fig. 1-2).

The morphologically left appendage, in contrast, is much narrower and tubular. It has a narrow junction with the remainder of the atrium, and one that is marked by neither terminal groove nor muscular crest. The pectinate muscles are confined within the morphologically left appendage, with the posterior aspect of the morphologically left vestibule, also containing the coronary sinus, being smooth walled as it merges with the pulmonary venous component (Fig. 1-3).

The morphological method also shows its value when applied to the ventricular mass, which extends from the atrioventricular to the ventriculo-arterial junctions. Within the ventricular mass as thus defined, there are almost always two ventricles. Description of ventricles, no matter how malformed they may be, is facilitated if they are analysed as possessing three components. These are, first, the inlet, extending from the atrioventricular junction to the distal attachment of the atrioventricular valvar tension

Figure 1-2 The short-axis view of the right atrioventricular junction from above, the atrium having been opened, with a cut parallel to the atrioventricular junction, and the wall of the appendage having been reflected, shows how the pectinate muscles within the appendage extend all round the vestibule of the tricuspid valve.

Figure 1-3 The short-axis view of the left atrioventricular junction from above, from the same heart as in Figure 1-2, shows the narrow entrance to the tubular appendage of the morphologically left atrium. The pectinate muscles are confined within the appendage, so that the inferior wall of the atrium is smooth. This contains the coronary sinus within the morphologically left atrioventricular junction. Note also the typical appearance of the morphologically left side of the septum.

Figure 1-4 The anterior wall has been removed to show the three component parts of the morphologically right ventricle, which extends from the atrioventricular to the ventriculo-arterial junctions (*dotted red lines*). The coarse apical trabeculations are the most constant of these features.

Figure 1-5 The posterior wall has been removed to show the three component parts of the morphologically left ventricle of the same heart as shown in Figure 1-4. This ventricle also extends from the atrioventricular to the ventriculo-arterial junctions (*dotted red line*), and the fine apical trabeculations are its most constant feature.

apparatus. The second part is the apical trabecular component. The third is the outlet component, supporting the leaflets of the arterial valve (Figs. 1-4 and 1-5).

Of these three components, it is the apical trabecular component that is most universally present in normal as well as in malformed and incomplete ventricles. Furthermore, it is the pattern of the apical trabeculations that differentiates morphologically right from left ventricles (see Figs. 1-4 and 1-5). This is the case even when the apical components exist as incomplete ventricles, lacking either inlet or outlet components, or sometimes both of these components (Fig. 1-6).

When the morphology of individual ventricles is identified in this fashion, all hearts with two ventricles can then be analysed according to the way in which the inlet and outlet components are shared between the apical trabecular components. In order fully to describe any ventricle,

Figure 1-6 In the heart illustrated, there is double inlet to and double outlet from a dominant left ventricle. The aorta and pulmonary trunk (PT) are seen arising in parallel fashion from the left ventricle, with the aorta anterior and to the left. On the anterior and right-sided shoulder of the dominant left ventricle, however, there is still a second chamber to be seen, fed through a ventricular septal defect. This chamber is the apical trabecular component of the right ventricle (RV), identified by its coarse trabeculations.

account must also be taken of its size. It is then necessary further to describe the way in which the two ventricles themselves are related within the ventricular mass. This feature is described in terms of ventricular topology, since two basic patterns are found that cannot be changed without physically taking apart the ventricular components and reassembling them. The two patterns are mirror images of each other. They can be conceptualised in terms of the way in which, figuratively speaking, the palmar surface of the hands can be placed upon the septal surface of the morphologically right ventricle. In the morphologically right ventricle of the normal heart, irrespective of its position in space, only the palmar surface of the right hand can be placed on the septal surface such that the thumb occupies the inlet and the fingers fit into the outlet (Fig. 1-7).

The palmar surface of the left hand then fits in comparable fashion within the morphologically left ventricle, but it is the right hand that is taken as the arbiter for the purposes of categorisation. The usual pattern, therefore, can be described as right hand ventricular topology.¹⁸ The other pattern, the mirror image of the right hand prototype, is then described as left hand ventricular topology. In this left hand pattern, seen typically in the mirror-imaged normal heart, or in the variant of congenitally corrected transposition found with usual atrial arrangement, it is the palmar surface of the left hand that fits on the septal surface of the morphologically right ventricle with the thumb in the inlet and the fingers in the outlet (Fig. 1-8).

Figure 1-7 The cartoon shows how the palmar surface of the right hand can be placed on the septal surface of the normal morphologically right ventricle with the thumb in the inlet component and the fingers extending into the ventricular outlet. This is the essence of right hand ventricular topology, also known as a d-ventricular loop.

Figure 1-8 This cartoon shows the mirror-imaged normal heart. In this setting, it is the palmar surface of the left hand that can be placed on the septal surface of the morphologically right ventricle with the thumb in the inlet and the fingers in the outlet. This is the essence of left hand topology, or the l-ventricular loop. Compare with Figure 1-7.

These two topological patterns can always be distinguished irrespective of the location occupied in space by the ventricular mass itself. A left hand pattern of topology, therefore, is readily distinguished from a ventricular mass with right hand topology in which the right ventricle has

Figure 1-9 The heart is opened in clamshell fashion to show that both atrioventricular valves enter the same ventricular chamber, which also gives rise to both outflow tracts. We were unable to find a second ventricular chamber. The exceedingly coarse apical trabeculations, and the absence of the second chamber, identify this heart as having a solitary ventricle of indeterminate morphology. This is the only true single ventricle.

been rotated to occupy a left-sided position. Component make-up, trabecular pattern, topology and size are independent features of the ventricles. On occasion, all may need separate description in order to remove any potential for confusion.

Only rarely will hearts be encountered with a solitary ventricle. Sometimes this may be because a right or left ventricle is so small that it cannot be recognised with usual clinical investigatory techniques. There is, nonetheless, a third pattern of apical ventricular morphology that is found in hearts possessing a truly single ventricle. This is when the apical component is of neither right nor left type, but is very coarsely trabeculated, and crossed by multiple large muscle bundles. Such a solitary ventricle has an indeterminate morphology (Fig. 1-9).

Analysis of ventricles on the basis of their apical trabeculations precludes the need to use illogically the term single ventricle or univentricular heart for description of those hearts with one big and one small ventricle. These hearts may have a functionally univentricular arrangement, but all chambers that possess apical trabecular components can be described as ventricles, be they big or small, and be they incomplete or complete. Any attempt to disqualify such chambers from ventricular state must lead to a system that is artificial. Only hearts with a truly solitary

ventricle need be described as univentricular, albeit that the connections of the atrioventricular junctions can be univentricular in many more hearts.

In determining the morphology of the great arteries, there are no intrinsic features which enable an aorta to be distinguished from a pulmonary trunk, or from a common or solitary arterial trunk. The branching pattern of the trunks themselves, nonetheless, is sufficiently characteristic to permit these distinctions (Fig. 1-10).

The aorta gives rise to at least one coronary artery and the bulk of the systemic arteries. The pulmonary trunk gives rise directly to both, or one or the other, of the pulmonary arteries. A common trunk supplies directly the coronary, systemic and pulmonary arteries. A solitary arterial trunk exists in the absence of the proximal portion of the pulmonary trunk. In such circumstances, it is impossible to state with certainty whether the persisting trunk is common or aortic. Even in the rare cases that have transgressed one of these rules, examination of the overall branching pattern has always permitted us to distinguish the nature of the arterial trunk.

ATRIAL ARRANGEMENT

The cornerstone of any system of sequential analysis must be accurate establishment of atrial arrangement, since this is the starting point for subsequent analysis. When arrangement of the atriums is assessed according to the morphology of the junction of the appendages with the rest of the atriums,¹⁹ then since all hearts have two atrial appendages, each of which can only be of morphologically right or left type, there are only four possible patterns of arrangement (Fig. 1-11).

The most common is the usual arrangement, also called *situs solitus*, in which the morphologically right appendage is right-sided, and the morphologically left appendage is left-sided. The second arrangement, very rare, is the mirror image of the usual. It is often called *situs inversus*, even though the atrial chambers are not upside down. In these two arrangements, the appendages are lateralised, with the morphologically right appendage being to one side, and the morphologically left appendage to the other. The two other arrangements do not show such lateralisation. Instead, there is isomerism of the atrial appendages. In these patterns, the two appendages are mirror images of each other, with morphological characteristics at their

Figure 1-10 The cartoon shows how the branching pattern of arterial trunks permits their distinction. The solitary arterial trunk is described when the intrapericardial pulmonary arteries are absent, since in this setting it is impossible to determine, had they been present, whether they would have taken origin from the heart, making the trunk an aorta, or from the trunk itself, in which case there would have been a common arterial trunk with pulmonary atresia.

Figure 1-11 The cartoon shows how, when analysed on the basis of the extent of the pectinate muscles relative to the atrioventricular vestibules (see Figures 1-2 and 1-3), there are only four possible ways in which the two atrial appendages can be arranged. Note, however, that the venoatrial connections can show marked variation, particularly in the isomeric settings, also known collectively as visceral heterotaxy.

junctions with the rest of the atriums on both sides of either right type or left type.

RECOGNITION OF ATRIAL ARRANGEMENT

The arrangement of the appendages, ideally, is recognised by direct examination of the extent of the pectinate muscles round the vestibules (see Figs. 1-2 and 1-3). This feature should now be recognisable using cross sectional echocardiography, particularly from the transoesophageal window. In most clinical situations, however, it is rarely necessary to rely only on direct identification. This is because, almost always, the morphology of the appendages is in harmony with the arrangements of the thoracic and abdominal organs. In patients with lateralised arrangements, that is the usual and mirror imaged patterns, it is exceedingly rare for there to be disharmony between the location of the organs (Fig. 1-12).

When the appendages are isomeric, in contrast, then the abdominal organs are typically jumbled-up (Fig. 1-13).

Even when there is such abdominal heterotaxy, the lungs and bronchial tree are almost always symmetrical, and it is rare for the bronchial arrangement to show disharmony with the morphology of the appendages. The presence of isomerism, therefore, can almost always be inferred from the bronchial anatomy. The morphologically left bronchus is long, and it branches only after it has been crossed by its accompanying pulmonary artery, making the bronchus hyparterial. In contrast, the morphologically right bronchus is short, and is crossed by its pulmonary artery only after it has branched, giving an eparterial pattern of branching. The four patterns of bronchial branching are then almost always in harmony with the arrangement of the atrial appendages. Similar inferences to those provided from bronchial arrangement can also usually be obtained non-invasively by using cross-sectional ultrasonography to image the abdominal great vessels. These vessels bear a distinct relation to each other, and to the spine, which generally reflects bodily arrangement, although not as accurately as does bronchial anatomy. The vessels can be distinguished ultrasonically according to their pattern of pulsation. When the atriums are lateralised, then

Figure 1-12 The cartoon shows the usual and mirror-imaged arrangements of the organs, which are lateralised. Almost always there is harmony between the arrangement of the right and left atrial appendages (RAA, LAA) and the remaining thoraco-abdominal organs. The numbers show the three lobes of the morphologically right lung, and the two lobes of the morphologically left lung.

Figure 1-13 This cartoon shows the typical features of the thoraco-abdominal organs in so-called visceral heterotaxy. The abdominal organs are jumbled up, but the lungs and atrial appendages are usually isomeric, having the same morphological features on the right and left sides. It is usual for right isomerism to be associated with absence of the spleen, and left isomerism with multiple spleens, but these associations are far from constant. Thus, different pictures emerge when visceral heterotaxy is subdivided on the basis of isomersim as opposed to splenic morphology. Cardiac assessment, however, should start with analysis of atrial morphology based on the structure of the atrial appendages.

almost without exception the inferior caval vein and aorta lie to opposite sides of the spine, with the caval vein on the side of the morphologically right appendage. When there is isomerism, then the great vessels usually lie to the same side of the spine, with the caval vein in anterior position in those with isomerism of the right atrial appendages, and posterior, or with the azygos vein posterior, in those having isomerism of the left atrial appendages.

Generally speaking, isomerism of the right atrial appendages is associated with absence of the spleen, while isomerism of the left atrial appendages is associated with multiple spleens. Patients with isomerism of the atrial appendages, therefore, are frequently grouped together, from the cardiac standpoint, under the banner of the splenic syndromes. This approach is much less accurate than describing the syndromes directly in terms of isomerism of the atrial appendages, since the correlation between isomerism of the right

atrial appendages and absence of the spleen, and between isomerism of the left atrial appendages and multiple spleens, is far from perfect.²⁰ Isomerism of the right and left appendages, in contrast, describes what is there, and additionally serves to concentrate attention upon the heart.

THE ATRIOVENTRICULAR JUNCTIONS

In the normal heart, the atrial myocardium is contiguous with the ventricular mass around the orifices of the mitral and tricuspid valves. Electrical insulation is provided at these junctions by the fibrofatty atrioventricular grooves, other than at the site of the penetration of the bundle of His. In order to analyse accurately the morphology of the atrioventricular junctions in abnormal hearts, it is first necessary to know the morphology of the ventricular mass so as to establish which atrium is connected to which ventricle. With this information to hand, it is then possible to define the specific patterns of union or non-union across the junctions, and to determine the morphology of the valves guarding the atrioventricular junctions. In hearts with complex malformations, it is also necessary on occasion to describe the precise topology of the ventricular mass, and to specify the relationships of the ventricles themselves.

PATTERNS OF UNION OR NON-UNION OF THE ATRIAL AND VENTRICULAR CHAMBERS

As already described, the patterns depend on the way that the myocardium of both atriums is joined to the ventricular myocardium around the entirety of the atrioventricular junctions, the atrial and ventricular muscle masses being separated from the electrical standpoint by the insulating fibrofatty tissues of the junctions other than at the site of the atrioventricular bundle. The cavities of the atrial chambers, therefore, are potentially connected to the underlying ventricular cavities via the atrioventricular orifices. In every heart, perforce, since there are two atrial chambers, there is the possibility for two atrioventricular connections, which will be right sided and left sided (Fig. 1-14).

Figure 1-14 This four-chamber section of the normal heart shows the paired atrioventricular junctions (*red double-headed arrows*) across which the cavities of the atrial chambers are connected to their appropriate ventricles.

Figure 1-15 This heart has an atrioventricular septal defect with common atrioventricular junction (*red brace*). The presence of the common junction, however, does not disguise the fact that each atrium is joined to its own ventricle across paired junctions, albeit now guarded by a common valve.

This is the case irrespective of whether the junctions themselves are guarded by two valves (see Fig. 1-14) or a common valve (Fig. 1-15).

One of the junctions may be blocked by an imperforate valvar membrane, but this does not alter the fact that, in such a setting, there are still two potential atrioventricular connections (Fig. 1-16).

In some hearts, in contrast, this possibility is not fulfilled. This is because one of the connections is completely absent. Then, the atrial myocardium on that side has no connection with the underlying ventricular myocardium, being separated from the ventricular mass by much more extensive

Figure 1-16 The atrioventricular junctions have been sectioned in four-chamber fashion in this heart with combined tricuspid and pulmonary atresia. In this instance, unusually, the tricuspid atresia is the consequence of an imperforate right atrioventricular valve, shown by the *short red brace*. The *longer brace* shows the patent left atrioventricular connection, through which the left atrium drains to the left ventricle. The atrioventricular connections, therefore, are potentially concordant (compare with Fig. 1-17). RV, right ventricle.

Figure 1-17 This heart, with the usual form of tricuspid atresia, has also been sectioned in four-chamber fashion. Only three chambers, however, are seen. This is because the essence of typical tricuspid atresia, and many patients with mitral atresia, is absence of an atrioventricular connection, in this instance the right atrioventricular connection (blue dotted line).

formation than normal of the fibrofatty tissues of the atrioventricular groove. This arrangement is the most common pattern producing atrioventricular valvar atresia (Fig. 1-17).

When atrioventricular connections are defined in this fashion, all hearts fit into one of three groups. In the first group, by far the most common, the cavity of each atrial chamber is joined actually or potentially, but separately, to that of an underlying ventricle. The feature of the second group is that only one of the ventricles, if indeed two are present, is in communication with the atrial cavities. There is then an even rarer third group. This is seen when one atrioventricular connection is absent, and the solitary atrioventricular junction, via a straddling valve, is connected to two ventricles. This arrangement is uniatrial but biventricular.

There are three possible arrangements in hearts with each atrium joined to its own ventricle. Put in another way, there are three types of biventricular atrioventricular connection. These depend on the morphology of the chambers connected together. The first pattern is seen when the atriums are joined to morphologically appropriate ventricles, irrespective of the topology or relationship of the ventricles, or of the morphology of the valves guarding the junctions. This arrangement produces concordant atrioventricular connections. Such concordant connections can be found with either usually arranged atrial appendages, or in the mirror-imaged arrangement (Fig. 1-18).

The second arrangement is the reverse of the first. It is again independent of relationships or valvar morphology. It produces discordant atrioventricular connections, and can again be found in the usual or mirror-imaged situations, albeit that, when the atrial appendages are mirror-imaged in patients with discordant atrioventricular connections,

Figure 1-18 The cartoon shows how concordant atrioventricular connections can exist in usual and mirror-imaged patterns. Almost without exception, atriums with usually arranged appendages are joined to a ventricular mass with right hand topology, whilst atriums with mirror-imaged appendages are joined to a ventricular mass with left hand topology. It is only when these features are not present that it is necessary always to state the topology of the ventricles.

the ventricles are typically in their expected pattern—in other words show right hand topology (Fig. 1-19).

These first two arrangements (see Figs. 1-18 and 1-19) are found when the atrial appendages are lateralised. The other biventricular atrioventricular arrangement, in which each atrium is joined to a separate ventricle, is found in hearts with isomeric appendages, be they of right or left morphology. Because of the isomeric nature of the appendages, this third arrangement cannot accurately be described in terms of concordant or discordant connections. It is a discrete biventricular pattern in its own right, which is mixed (Fig. 1-20). It, too, is independent of ventricular relationships and atrioventricular valvar morphologies, and requires specification of ventricular topology to make the description complete.

There are also three possible junctional arrangements that produce univentricular atrioventricular connections (Fig. 1-21). The first is when the cavities of right- and left-sided atrial chambers are connected directly to the same ventricle. This is called double inlet atrioventricular connection, irrespective of whether the right- and left-sided atrioventricular junctions are guarded by two atrioventricular

Figure 1-19 The cartoon shows the arrangements that, almost without exception, produce discordant atrioventricular connections.

Figure 1-20 In the setting of isomeric atrial appendages, with right isomerism as shown in the cartoon, biventricular connections of necessity are mixed irrespective of ventricular topology. Fully to describe these patterns, therefore, it is necessary to specify both the morphology of the atrial appendages and the ventricular topology.

valves or a common valve. The other two arrangements exist when one atrioventricular connection is absent, giving absent right-sided and absent left-sided atrioventricular connection, respectively. The patterns across the junctions that produce univentricular atrioventricular connections are different from those found with biventricular connections. Not only are they independent of ventricular relationships and valvar morphology, but they are also independent of atrial and ventricular morphologies. Hearts with concordant or discordant atrioventricular connections can only exist when usually arranged or mirror-imaged atrial chambers are each joined to separate ventricles. A heart with biventricular mixed connection can only be found when each of two atrial chambers having isomeric appendages

is joined to a separate ventricle. In contrast, double inlet, absent right-sided, or absent left-sided atrioventricular connections can be found with usually arranged, mirror-imaged or isomeric atrial appendages. Each type of uni-ventricular atrioventricular connection can also be found with the atriums connected to a dominant right ventricle, a dominant left ventricle, or a morphologically indeterminate ventricle (see Fig. 1-21).

Ventricular morphology must always, therefore, be described separately in those hearts in which the atrial chambers are joined to only one ventricle. Although, in these hearts, only one ventricle is joined to the atriums, in most of them there is a second ventricle present. This second ventricle, of necessity incomplete, will be of complementary trabecular pattern to that of the dominant ventricle. Most frequently, the dominant ventricle is a left ventricle, and the incomplete ventricle possesses right ventricular apical trabeculations. More rarely, the dominant ventricle is morphologically right, with the incomplete ventricle being morphologically left. Even more rarely, hearts will be found with a solitary ventricular chamber of indeterminate morphology (see Fig. 1-9). In clinical practice, seemingly solitary left or right ventricles may be encountered when the complementary incomplete ventricle is too small to be demonstrated.

ARRANGEMENTS OF THE ATRIOVENTRICULAR VALVES

Describing the fashion in which the atriums are joined to the ventricles across the atrioventricular junctions accounts only for the way in which the atrial musculature inserts into the base of the ventricular mass. The morphology of the valves guarding the overall atrioventricular junctional area is independent of this feature, within the constraints

Figure 1-21 The cartoon shows some of the potential univentricular atrioventricular connections. In reality, these can exist with any arrangement of the atrial appendages (upper row), with double inlet, absent right or absent left atrioventricular (AV) connections (middle row) and with dominant left or right ventricles (LV, RV), or solitary and indeterminate ventricle (bottom row). The middle and bottom rows are illustrated with usual appendages simply for convenience. There is further variability with regard to the position of the incomplete ventricle, and with ventriculo-arterial connections, and so on. These hearts, therefore, exemplify the need for full sequential segmental analysis and description.

Figure 1-22 The cartoon shows the influence of an overriding atrioventricular (AV) junction on the precise arrangement of the connections. When the lesser part of the overriding junction is attached to the dominant ventricle, then the connections are effectively biventricular, and concordant in the example shown in the *left panel*. When the lesser part is committed to the incomplete ventricle, in contrast, then the connection is effectively double inlet, and to the left ventricle in the illustration (*right panel*). Any combination of atrial chambers and ventricles can be found with such straddling and overriding valves.

imposed by the pattern of the junctions itself. When the cavities of both atria are joined directly to the ventricular mass, the right- and left-sided atrioventricular junctions may be guarded by two patent valves (see Fig. 1-14), by one patent valve and one imperforate valve (see Fig. 1-16), by a common valve (see Fig. 1-15), or by straddling and overriding valves (Fig. 1-22).

These arrangements of the valves can be found with concordant, discordant, biventricular and mixed or double inlet types of connection. Either the right- or the left-sided valve may be imperforate, producing atresia but in the setting of a potential as opposed to an absent atrioventricular connection. A common valve guards both right- and left-sided atrioventricular junctions, irrespective of its morphology. A valve straddles when its tension apparatus is attached to both sides of a septum within the ventricular mass. It overrides when the atrioventricular junction is connected to ventricles on both sides of a septal structure. A right-sided valve, a left-sided valve, or a common valve can straddle, can override, or can straddle and override. Very rarely, both right- and left-sided valves may straddle and/or override in the same heart.

When one atrioventricular connection is absent, then the possible modes of connection are greatly reduced. This is because there is a solitary right- or left-sided atrioventricular connection and, hence, a solitary atrioventricular valve. The single valve is usually committed in its entirety to one ventricle. More rarely, it may straddle, override, or straddle and override. These latter patterns produce the extremely rare group of uniaxial but biventricular connections (Fig. 1-23).

A valve that overrides has an additional influence on description. This is because the degree of commitment of the overriding atrioventricular junction to the ventricles on either side of the septum determines the precise fashion in which the atria and ventricles are joined together. Hearts with two valves, in which one valve is overriding, are anatomically intermediate between those with, on the one hand, biventricular and, on the other hand, univentricular atrioventricular connections. There are two ways of describing such hearts. One is to consider the hearts as representing a special type of atrioventricular connection.

Figure 1-23 The cartoon illustrates tricuspid atresia due to absence of the right atrioventricular connection associated with straddling and overriding of the left atrioventricular valve. This produces an atrioventricular connection that is uniaxial but biventricular. The connection can be found with any combination of atrial arrangement and ventricular topology.

The alternative is to recognise the intermediate nature of such hearts in a series of anomalies, and to split the series depending on the precise connection of the overriding junction. For the purposes of categorisation, only the two ends of the series are labelled, with hearts in the middle being assigned to one or other of the end-points. We prefer this second option (see Fig. 1-22). When most of an overriding junction is connected to a ventricle that is also joined to the other atrium, we designate the pattern as being double inlet. If the overriding junction is connected mostly to a ventricle not itself joined to the other atrium, then each atrium is categorised as though joined to its own ventricle, giving the possibility of concordant, discordant, or mixed connections.

In describing atrioventricular valves, it should also be noted that the adjectives mitral and tricuspid are strictly accurate only in hearts with biventricular atrioventricular connections having separate junctions, each guarded by its own valve. In this context, the tricuspid valve is always found in the morphologically right ventricle, and the mitral valve in the morphologically left ventricle. In hearts with biventricular atrioventricular connections but with a common junction, in contrast, it is incorrect to consider the common valve as having mitral and tricuspid components, even when it is divided into right and left components. These right- and left-sided components, particularly on the left side, bear scant resemblance to the normal atrioventricular valves (see Chapter 27). In hearts with double inlet, the two valves are again better considered as right- and left-sided valves rather than as mitral or tricuspid. Similarly, although it is usually possible, when one connection is absent, to deduce the presumed nature of the remaining solitary valve from concepts of morphogenesis, this is not always practical or helpful. The valve can always accurately be described as being right or left sided. Potentially contentious arguments are thus defused when

the right- or left-sided valve straddles in the absence of the other atrioventricular connection, giving the uniatrial but biventricular connections.

VENTRICULAR TOPOLOGY AND RELATIONSHIPS

Even in the normal heart, the ventricular spatial relationships are complex. The inlet portions are more or less to the right and left, with the inferior part of the muscular ventricular septum lying in an approximately sagittal plane. The outlet portions are more or less anteroposteriorly related, with the septum between them in an approximately frontal plane. The trabecular portions extend between these two components, with the trabecular muscular septum spiraling between the inlet and outlet components. It is understandable that there is a desire to have a shorthand term to describe such complex spatial arrangements. We use the concept of ventricular topology for this purpose (see Figs. 1-7 and 1-8). In persons with usually arranged atriums and discordant atrioventricular connections, the ventricular mass almost always shows a left-handed topological pattern, whereas right-handed ventricular topology is usually found with the combination of mirror-imaged atriums and discordant atrioventricular connections. Although these combinations are almost always present, exceptions can occur. When noting such unexpected ventricular relationships as a feature independent of the topology, we account for right-left, anterior-posterior and superior-inferior coordinates. And, should it be necessary, we describe the position of the three ventricular components separately, and relative to each other.

In hearts with disharmonious arrangements in the setting of usual atrial arrangement and discordant atrioventricular connections, the distal parts of the ventricles are usually rotated so that the morphologically right ventricular trabecular and outlet components are to the right of their morphologically left ventricular counterparts, giving the impression of normal relationships. In such criss-cross hearts seen with usual atrial arrangement and concordant atrioventricular connections, the ventricular rotation gives a spurious impression of left-handed topology. In cases with extreme rotation, the inlet of the morphologically right ventricle may also be right sided in association with discordant atrioventricular connections. Provided that relationships are described accurately, and separately, from the connections and the ventricular topology, then none of these unusual and apparently complex hearts will be difficult either to diagnose or to categorise. In addition to these problematic criss-cross hearts, we have already discussed how description of ventricular topology is essential when accounting for the combination of isomeric appendages with biventricular mixed atrioventricular connections. This is because, in this situation, the same terms would appropriately be used to describe the heart in which the left-sided atrium was connected to a morphologically right ventricle as well as the heart in which the left-sided atrium was connected to a morphologically left ventricle. The arrangements are differentiated simply by describing also the ventricular topology.

Both the position and the relationships of incomplete ventricles need to be described in hearts with univentricular atrioventricular connections. Here, the relationships

are independent of both the connections and the ventricular morphology. While, usually, the incomplete right ventricle is anterior and right sided in classical tricuspid atresia, it can be anterior and left sided without in any way altering the clinical presentation and haemodynamic findings. Similarly, in hearts with double inlet ventricle, the position of the incomplete ventricle plays only a minor role in determining the clinical presentation. While a case can be made for interpreting such hearts with univentricular atrioventricular connections on the basis of presumed morphogenesis in the setting of right- or left-handed topologies, there are sufficient exceptions to make this approach unsuitable in the clinical setting. When we describe the position of incomplete ventricles, therefore, we simply account for their location relative to the dominant ventricle, taking note again when necessary of right-left, anterior-posterior and superior-inferior coordinates. On occasion, it may also be advantageous to describe separately the position of trabecular and outlet components of an incomplete ventricle.

THE VENTRICULO-ARTERIAL JUNCTIONS

Most polemics concerning the ventriculo-arterial junctions devolved upon the failure to distinguish between the way the arterial trunks arose from the ventricular mass as opposed to their relations to each other, along with undue emphasis on the nature of the infundibulums supporting their arterial valves. When these features are described independently, following the precepts of the morphological method, then all potential for disagreement is removed.

Origin of the Arterial Trunks from the Ventricular Mass

As with analysis of the atrioventricular junctions, it is necessary to account separately for the way the arteries take origin, and the nature of the valves guarding the ventriculo-arterial junctions. There are four possible types of origin. Concordant ventriculo-arterial connections exist when the aorta arises from a morphologically left ventricle, and the pulmonary trunk from a morphologically right ventricle, be the ventricles complete or incomplete. The arrangement where the aorta arises from a morphologically right ventricle or its rudiment, and the pulmonary trunk from a morphologically left ventricle or its rudiment, produces discordant ventriculo-arterial connections. Double outlet connection is found when both arteries are connected to the same ventricle, which may be of right ventricular, left ventricular or indeterminate ventricular pattern. As with atrioventricular valves, overriding arterial valves (see below) are assigned to the ventricle supporting the greater parts of their circumference. The fourth ventriculo-arterial connection is single outlet from the heart. This may take one of four forms. A common trunk exists when both ventricles are connected via a common arterial valve to one trunk that gives rise directly to the coronary arteries, at least one pulmonary artery, and the majority of the systemic circulation. A solitary arterial trunk exists when it is not possible to identify any remnant of an atretic pulmonary trunk within the pericardial cavity. The other forms of single outlet are single pulmonary trunk with aortic atresia, and single aortic trunk with pulmonary atresia. These latter two categories describe

only those arrangements in which, using clinical techniques, it is not possible to establish the precise connection of the atretic arterial trunk to a ventricular cavity. If its ventricular origin can be established, but is found to be imperforate, then the connection is described, along with the presence of an imperforate valve (see below). It is also necessary in hearts with single outlet to describe the ventricular origin of the arterial trunk. This may be exclusively from a right or a left ventricle, but more usually the trunk overrides the septum, taking its origin from both ventricles.

There are fewer morphologies for the valves at the ventriculo-arterial than at the atrioventricular junctions. A common arterial valve can only exist with a specific type of single outlet, namely common arterial trunk. Straddling of an arterial valve is impossible because it has no tension apparatus. Thus, the possible patterns are two perforate valves, one or both of which may override, or one perforate and one imperforate valve. As with overriding atrioventricular valves, the degree of override of an arterial valve determines the precise origin of the arterial trunk from the ventricular mass, the overriding valve, or valves, being assigned to the ventricle supporting the greater part of its circumference. For example, if more than half of an overriding pulmonary valve was connected to a right ventricle, the aorta being connected to a left ventricle, we would code concordant connections. If more than half the overriding aortic valve was connected to the right ventricle in this situation, we would code double outlet connections. In this way, we avoid the necessity for intermediate categories. The precise degree of override, nonetheless, is best stated whenever an overriding valve is found. This is done to the best of one's ability, using whichever techniques are available, and recognising the subjective nature of the task. In this setting, as with atrioventricular connections, we err on the side of the more usually encountered pattern.

Arterial Relationships

Relationships are usually described at valvar level, and many systems for nomenclature have been constructed on this basis. Indeed, the concept that the position of the arterial valves reflected ventricular topology^{5,6} became so entrenched that it became frequent to see d-transposition used as though synonymous with all combinations of concordant atrioventricular and discordant ventriculo-arterial connections. In the same way, l-transposition was used as a synonym for congenitally corrected transposition. In reality, we now know that the relationships of the arterial valves are a poor guide to ventricular topology. Describing arterial valvar position in terms of leftness and rightness also takes no cognisance of anteroposterior relationships, an omission particularly since, for many years, an anterior position of the aorta was used as the cornerstone for definitions of transposition.²¹ It is, therefore, our practice to describe arterial valvar relationships in terms of both right-left and anterior-posterior coordinates. Such description can be accomplished with as great a degree of precision as is required. A good system is the one that describes aortic position in degrees of the arc of a circle constructed around the pulmonary valve.¹⁸ Aortic valvar position is described relative to the pulmonary trunk in terms of eight positions of a compass, using the simple terms left, right, anterior, posterior, and side-by-side in their various combinations.

So long as we then remember that these describe only arterial-valvar relations, and convey no information about either the origin of the arterial trunks from the ventricular mass, or the morphology of the ventricular outflow tracts, we have no fear of producing confusion.

From the stance of positions of the arterial trunks, the possibilities are either for the pulmonary trunk to spiral round the aorta as it ascends from the base of the ventricles, or for the two trunks to ascend in parallel fashion. It is rarely necessary to describe these relationships. Spiralling trunks are associated most frequently with concordant ventriculo-arterial connections, and parallel trunks with discordant or double outlet connections, but again there is no predictive value in these relationships. In almost all hearts, the aortic arch crosses superiorly to the bifurcation of the pulmonary arteries.

An unexpected position of the aortic arch is a well-recognised associated anomaly of conditions such as tetralogy of Fallot (Chapter 36) or common arterial trunk (Chapter 41). In this respect, distinction should be made between the position of the arch and the side of the descending aorta, particularly in describing vascular rings (Chapter 47). The side of the aortic arch depends on whether it passes to the right or the left of the trachea. The position of the descending aorta is defined relative to the vertebral column.

Infundibular Morphology

The infundibular regions are no more and no less than the outlet components of the ventricular mass, but they have been the dwelling place of two of the sacred cows of paediatric cardiology. One is the so-called bilateral conus. In the past, this was often considered an arbiter of the ventriculo-arterial connection when associated with double outlet right ventricle, but ignored when each great artery with its complete muscular infundibulum was supported by its own ventricle. The other was the enigmatic crista, sought here and there as was the Scarlet Pimpernel, and just as elusive.²² If the infundibular structures are recognised for what they are, and their morphology described as such, then they, too, provide no problems in recognition and description. The morphology of the ventricular outlet portions is variable for any heart. Potentially, each ventricle can possess a complete muscular funnel as its outlet portion, and then each arterial valve can be said to have a complete infundibulum. When considered as a whole, the outlet portions of the ventricular mass in the setting of bilateral infundibulums have three discrete parts (Fig. 1-24).

Two of the parts form the anterior and posterior halves of the funnels of muscle supporting the arterial valves. The anterior, parietal, part is the free anterior ventricular wall. The posterior part is the inner heart curvature, a structure that separates the leaflets of the arterial from those of the atrioventricular valves. We term this component the ventriculo-infundibular fold. The third part is the septum that separates the two subarterial outlets, which we designated the outlet, or infundibular, septum. The dimensions of the outlet septum are independent of the remainder of the infundibular musculature. Indeed, it is possible, albeit rarely, for both arterial valves to be separated from both atrioventricular valves by the ventriculo-infundibular fold, but for the

Figure 1-24 The illustration shows the complete cone of musculature supporting both arterial valves in the setting of double outlet right ventricle with bilateral infundibulums and subaortic interventricular communication. The cones have parietal parts, outlined in red, posterior parts adjacent to the atrioventricular junctions, outlined in blue, and a part that divides them, outlined in yellow. The posterior part is the ventriculo-infundibular fold, separating the leaflets of the atrioventricular and arterial valves, whilst the dividing part is the outlet septum, interposed between the leaflets of the arterial valves.

arterial valves to be in fibrous continuity with one another because of the absence of the outlet septum. In most hearts, however, some part of the infundibular musculature is effaced, so that fibrous continuity occurs between the leaflets of one of the arterial and the atrioventricular valves. Most frequently, it is the morphologically left ventricular part of the ventriculo-infundibular fold that is attenuated. As a result, there is fibrous continuity between the leaflets of the mitral valve and the arterial valve supported by the left ventricle. Whether the arterial valve is aortic or pulmonary will depend on the ventriculo-arterial connections present. In the usual arrangement, the morphologically right ventricular part of the ventriculo-infundibular fold persists, so that there is tricuspid-arterial valvar discontinuity. Depending on the integrity of the outlet septum, there is usually a completely muscular outflow tract, or infundibulum, in the morphologically right ventricle. When both outlet portions are connected to the morphologically right ventricle, then most frequently the ventriculo-infundibular fold persists in its entirety, and there is discontinuity bilaterally between the leaflets of the atrioventricular and arterial valves. But many hearts in which both arterial valves are connected unequivocally to the right ventricle have fibrous continuity between at least one arterial valve and an atrioventricular valve. It makes little sense to deny the origin of both arterial trunks from the right ventricle in this setting. This situation is yet another example of the controversy generated when one feature of cardiac morphology is determined on the basis of a second, unrelated, feature. When both arterial trunks take their origin from the morphologically left ventricle, the tendency is for there to be continuity between the leaflets of both arterial valves and both atrioventricular valves. Even then, in some instances the ventriculo-infundibular fold may persist in part or in its whole.

It is usually the state of the ventriculo-infundibular fold, therefore, that is the determining feature of infundibular morphology. Ignoring the rare situation of complete absence of the outlet septum, and considering morphology from the standpoint of the arterial valves, there are four possible arrangements. First, there may be a complete

subpulmonary infundibulum, with continuity between the leaflets of the aortic and the atrioventricular valves. Second, there may be a complete subaortic infundibulum, with continuity between the pulmonary and the atrioventricular valves. Third, there may be bilateral infundibulums, with absence of continuity between the leaflets of the arterial and the atrioventricular valves. Fourth, there may be bilaterally deficient infundibulums, with continuity bilaterally between the arterial and the atrioventricular valves. In themselves, these terms are not specific. For specificity, it is also necessary to know which arterial valve takes origin from which ventricle. This emphasises the fact that infundibular morphology is independent of the ventriculo-arterial connections.

The above discussion has been concluded without any mention of the enigmatic crista. This is because, when used in reference to malformed hearts, the term has had so many definitions as to render it virtually meaningless. We reserve the term supraventricular crest for the normal heart, or for hearts with a normally structured right ventricular outflow tract. The crest is then the muscular ventricular roof that separates the attachments of the leaflets of the tricuspid and pulmonary valves. The greater part of this fold is made up of the right ventricular component of the ventriculo-infundibular fold, including the free-standing sleeve of subpulmonary infundibulum. Only a small part of its most medial edge is the muscular outlet septum. This cannot be distinguished in its own right when the outflow tract is normally structured. The supraventricular crest of the normal heart as thus defined is discrete and separate from the extensive muscular trabeculation that reinforces the septal surface of the morphologically right ventricle. This structure divides into two limbs, which clasp the body of the supraventricular crest. We call this extensive muscular strap the septomarginal trabeculation, but others recognise it as the septal band. These three structures, the ventriculo-infundibular fold, outlet septum, and the septomarginal trabeculation, can be so well aligned that it is not possible to say where one starts and the other finishes. In hearts with ventricular septal defects, or abnormal ventriculo-arterial connections, the three parts are frequently widely separated. Each can then be clearly recognized in its own right. The problem with the term crista is that, at some time or in some place, it has been used to describe each of these three different structures. It is for this reason that we restrict its use to the normal heart. In abnormal hearts, we describe each muscle bundle in its own right. Any muscular structure that interposes between the ventricular outflow portions is called the outlet septum. Any muscular structure separating the attachments of the leaflet of an arterial valve from that of an atrioventricular valve is called the ventriculo-infundibular fold. The extensive muscular strap in the morphologically right ventricle is described as the septomarginal trabeculation. We also take note of the series of muscle bundles that radiate from the anterior margin of the septomarginal trabeculation, and term these septoparietal trabeculations.

ASSOCIATED MALFORMATIONS

A majority of patients seen with congenitally malformed hearts will have their cardiac segments joined together in usual fashion, together with normal morphology and relations. In such a setting, the associated malformation

will be the anomaly. The body of this book is concerned with describing the specific morphological and clinical features of these anomalies. It is also necessary, nonetheless, to pay attention to the position of the heart within the chest, and the orientation of the cardiac apex. It is also necessary to recognise that the heart may be positioned ectopically outside the thoracic cavity. An abnormal position of the heart within the chest is another associated malformation, and should not be elevated to a prime diagnosis. This is not to decry the importance of an abnormal cardiac position, if only to aid in interpretation of the electrocardiogram. Knowing that the heart is malpositioned, however, gives no information concerning its internal architecture. Full sequential segmental analysis is needed to establish the cardiac structure, and not the other way round. The heart can be located mostly in the left hemithorax, mostly in the right hemithorax, or centrally positioned in the mediastinum. The cardiac apex can then point to the left, to the right, or to the middle. The orientation of the apex is independent of cardiac position. And both of these are independent of the arrangement of the atrial appendages, and of the thoracic and abdominal organs. Describing a right-sided heart, with leftward apex, should be understandable by all, even including the patient!

These two seminal works were the first to suggest that a logical approach be adopted to so-called complex congenital cardiac malformations. Prior to these innovative publications, the complicated malformations had usually been grouped together in a miscellaneous category. These important investigations showed that the lesions were amenable to logical analysis.

These reviews represented the initial steps taken by the European school of nomenclaturists to refine the segmental approach to diagnosis. The Europeans shifted emphasis from the segments themselves, whilst still recognising the importance of segmental morphology, but pointing out at the same time the need to assess the way the components of the segments were joined together, or in some instances not joined together.

- Anderson RH, Becker AE, Tynan M, et al: The univentricular atrioventricular connection: Getting to the root of a thorny problem. *Am J Cardiol* 1984;54:822–882.

In these two reviews, the European school, supported now also by the late Robert Freedom, recognised the wisdom of the morphological method. They pointed out that, in so-called hearts with single ventricles, or univentricular hearts, it was very rare for the ventricular mass to contain but one chamber. In fact, it was the atrioventricular connections that were univentricular in these settings. Since then, the European school has based its definitions exclusively on the morphological method, as explained at length in this chapter.

- Jacobs ML, Anderson RH: Nomenclature of the functionally univentricular heart. *Cardiol Young* 2006;16(Suppl 1):3–8.

This review showed how, by the addition of a simple adverb, namely functionally, it was possible to defuse all the multiple arguments that continued to surround so-called hearts with single ventricles. Most such hearts have one big and one small ventricle. The key point is that only the big ventricle is capable of supporting one or the other of the circulations, or in most instances both circulations. Hence, the arrangement, whilst not anatomically univentricular, is certainly functionally univentricular.

- Van Praagh R, David I, Wright GB, Van Praagh S: Large RV plus small LV is not single LV. *Circulation* 1980;61:1057–1058.

This crucial concept, stated in a letter to the Editor, identified a crucial flaw in the approach taken by the European school when analysing patients with alleged single ventricles, or univentricular hearts. The authors pointed out that it was philosophically unsound to base definitions of a given structure on one of its parts that was variable. Instead, they established the crucial principle of the morphological method, recommending that the structures be identified on the basis of their most constant components.

It is axiomatic that, to understand abnormal anatomy and to describe it adequately, it is necessary to understand normal cardiac anatomy, including the relationships of the conduction tissues and coronary arteries to the various components of the heart. I review these features in this chapter. An appreciation of normal anatomy is the key to the understanding of the terms and concepts outlined in the previous chapter. The changes in these features of normality in congenitally malformed hearts will then be emphasised in the various chapters within the book concerned with specific lesions. At this stage, I place emphasis on the diagnostic features of the chambers that permit their recognition when the heart itself is congenitally malformed.

THE HEART WITHIN THE CHEST

My account begins with a description of the normal interrelationships of the chambers within the heart, and the location of the heart itself within the chest. The heart normally

occupies the middle compartment of the mediastinum, with two-thirds of its bulk to the left of the midline (Fig. 2-1). The long axis shows a considerable obliquity relative to the long axis of the body, extending roughly along a line drawn through the right shoulder to the left hemidiaphragm. Despite this discrepancy between the planes of the body and those of the heart, the cardiac structures should still be described relative to the bodily coordinates, that is, in attitudinally appropriate orientation, although this basic rule of anatomy has not always been followed.¹ Usually described in terms of a triangle, the true shape of the heart as projecting to the frontal surface is more trapezoidal, with horizontal upper and lower borders, a more or less vertical right border just outside the edge of the sternum and a sloping left border extending out to the apex in the fifth intercostal space (Fig. 2-2). The most instructive single plane to be found within the heart is the so-called base.

Figure 2-1 As shown by this cast of a normal heart superimposed on the frontal chest radiograph, the heart is a mediastinal structure with two-thirds of its bulk positioned to the left of the midline.

Figure 2-2 In considering the arrangement of the cardiac silhouette as seen in frontal projection as shown in Figure 2-1, it can best be likened to a trapezium, with a longer inferior border adjacent to the diaphragm. The trapezium itself can then be broken down into atrial (*red*) and ventricular (*blue*) triangles, with the ventricular triangle having its own base and apex, the latter corresponding with the cardiac apex.

Figure 2-3 The positions of the valves are shown within the cardiac silhouette, as seen in the frontal projection.

In this respect, the term base is itself used in various ways. The true base of the heart is the posterior aspect of the atrial chambers relative to the mediastinum. More usually, the term is applied to the base of the ventricular mass. A section along the short axis across this ventricular base contains all four cardiac valves. When viewed in an anatomically appropriate fashion from the front, the pulmonary valve is seen to be located superiorly and to the left, with the aortic, mitral and tricuspid valves overlapping when traced in rightward and inferior direction (Fig. 2-3). Interrogation of the short-axis section from the atrial aspect emphasises the central location of the aortic valve, with its leaflets, and their supporting aortic sinuses, being related to all of the cardiac chambers (Fig. 2-4).

Figure 2-4 The dissection shows the short axis of the heart viewed from its atrial aspect, and illustrates the keystone location of the aortic valve relative to the other cardiac valves.

Figure 2-5 The cartoon shows the arrangement of the pericardium relative to the heart as seen in the parasternal long-axis echocardiographic cut. The transverse sinus within the pericardial cavity lines the inner curvature, while the oblique sinus is behind the left atrium.

In considering the location of the heart, note should be taken of the pericardium, and the major nerves that cross it. The fibrous pericardium can be likened to a cardiac seat belt, with its attachments to the diaphragm, along with the entrances and exits of the great veins and arterial trunks, anchoring the heart within the mediastinum. The tough fibrous pericardial sac is lined with a serous layer, the parietal pericardium, which is itself reflected onto the surface of the heart as the epicardium. Two important recesses are found within the cavity, namely the transverse and oblique sinuses (Fig. 2-5).

Coursing through the mediastinum, and embedded within the fibrous pericardium, are the vagus and phrenic nerves (Fig. 2-6). Both sets of nerves traverse the length of the heart on each side, with the phrenic nerves anterior and the vagus nerves posterior to the hilums of the lungs. Note should also be taken of the recurrent laryngeal nerves, which pass round the brachiocephalic trunk on the right side and the arterial duct, or its ligamentous remnant, on the left. The thymus gland is also a prominent structure related to the anterior and lateral aspects of the pericardial sac in the region of exit of the great arterial trunks,

Figure 2-6 The heart is shown as seen by the surgeon through a median sternotomy. The locations of the vagus and phrenic nerves are shown relative to the opened pericardial sac.

Figure 2-7 The cavities of the heart have been cast in red for the so-called right chambers, and blue for the left chambers. The casts are positioned in attitudinally correct orientation, and show that, in reality, the right chambers are positioned anterior to their supposedly left counterparts. The tip of the left atrial appendage is the only part of the left atrium that projects to the frontal silhouette, and only a small strip of left ventricle is seen when the cardiac contour is viewed in frontal projection.

particularly in neonates and infants, while the oesophagus is, perhaps, the most important mediastinal structure related directly to the heart.

The Chambers within the Heart

The key to full understanding of cardiac anatomy is the realisation that the heart is not arranged in the upright fashion of a Valentine heart.¹ Instead, the long axis of the heart extends from right to left with considerable obliquity. When seen in frontal projection, the anterior surface of the silhouette is occupied for the most part by the right atrium and ventricle. The left atrium is almost entirely a posterior structure, with only its appendage projecting to the left upper border, while only a strip of left ventricle is seen down the sloping left border. The so-called right chambers of the heart, therefore, are basically anterior, with the ventricles situated to the left and inferiorly relative to their atrial counterparts (Fig. 2-7). The aortic and mitral valves are closely related one to the other within the base of the left ventricle, while the pulmonary and tricuspid valves are separated in the roof of the right ventricle by the extensive supraventricular crest, known classically in its Latin form as the crista supraventricularis. The crest itself is intimately related on its posterior aspect to the aortic valve and root. The diaphragmatic border of the ventricular mass, made up of the right ventricle, exhibits a sharp angle between the sternocostal and inferior surfaces, known as the acute margin. In contrast, the left border of the ventricular mass, formed by the left ventricle, has a much gentler curve, and is the obtuse margin. Important grooves are found within the various surfaces, namely the atrioventricular, or coronary, grooves, which more or less mark the cardiac short axis, and the interventricular grooves, which indicate the long axis, and mark the location of the ventricular septum. A particularly important point is found on the diaphragmatic surface, positioned inferiorly rather than posteriorly when the heart is located within the body, where the interventricular groove joins the atrioventricular groove. This is the so-called cardiac crux.

The Morphologically Right Atrium

The right atrium in the normal heart is recognised most readily as the chamber receiving the systemic venous return through the superior and inferior caval veins, along with the venous return from the heart itself through the coronary sinus. These channels open into the smooth-walled venous component of the atrium. In addition, the atrial chamber possesses a smooth-walled area that we described as the vestibule. This layer of muscle inserts into the leaflets of the tricuspid valve. The atrium also has a characteristic septal surface, and the extensive and trabeculated appendage (Fig. 2-8). It is the appendage that is the most constant part. This feature, therefore, should be used to permit recognition of the chamber as the morphologically right structure in congenitally malformed hearts. Recognition of structures according to their morphology rather than their location, and using their most constant part in final arbitration, is called the morphological method.² As I discussed in the previous chapter, this principle is the basis of logical analysis of congenitally malformed hearts.³

The characteristic external feature of the right appendage is its broad triangular shape (Fig. 2-9), along with its extensive junction with the smooth-walled venous component, this being marked by the terminal groove. Internally, the groove matches with the strap-like terminal crest (Fig. 2-10). Taking origin in parallel fashion from the crest and extending laterally into the appendage are the pectinate muscles. In the morphologically right atrium, these muscles extend all round the atrioventricular junction, reaching into the diverticulum located inferior to the orifice of the coronary sinus (Fig. 2-11). Although often considered to be sub-Eustachian, this diverticulum, also described as a sinus, is sub-Thebesian when the heart is seen in attitudinally appropriate position (see Fig. 2-11). The extent of the pectinate muscles relative to the vestibule of the right atrioventricular valve is the single most characteristic feature of the right atrium in congenitally malformed hearts.⁴ In many hearts, flap-like muscular or fibrous valves take origin from the extent of the terminal crest and guard the orifices of the inferior caval vein and

Figure 2-8 The morphologically right atrium has been opened by a cut through its appendage parallel to the right atrioventricular junction, and the wall of the appendage reflected upwards, revealing that the atrium, in addition to its appendage, possesses a vestibule along with the systemic venous sinus, and is separated by the septum from the left atrium.

Figure 2-9 The characteristic external feature of the morphologically right atrium is the triangular shape of its appendage, with the terminal groove (*red dotted line*) separating the appendage from the termination of the systemic venous tributaries in the systemic venous sinus.

Figure 2-10 This view of the interior of the morphologically right atrium, shown in attitudinally appropriate orientation, is taken in the operating room from a patient with a septal defect in the floor of the oval fossa. It shows the extensive terminal crest giving rise to the pectinate muscles. (Courtesy of Dr. Benson R. Wilcox, University of North Carolina, Chapel Hill.)

the coronary sinus. These are the Eustachian and Thebesian valves, respectively (see Fig. 2-11). The valves, however, are not uniformly present. An important structure in continuation with the Eustachian valve, nonetheless, can almost always be found. This is the tendon of Todaro,⁵ which runs

Figure 2-11 This view of the interior of the morphologically right atrium, made possible as in Figure 2-8 by making an extensive cut parallel to the atrioventricular junction, and reflecting the wall of the appendage superiorly, shows the location of the so-called venous valves, and the position of the sinus septum.

through the wall that separates the coronary sinus from the oval fossa, the so-called sinus septum, to insert into the fibrous root of the aorta. This tendon forms one of the borders of the triangle of Koch (see below).

At first sight, the septal surface of the right atrium is extensive, surrounding the oval fossa and incorporating the orifices of the superior caval vein and coronary sinus (see Figs. 2-8 and 2-11). This appearance is deceptive. Only the floor of the oval fossa, along with its antero-inferior rim, is made up of tissues that separate the cavities of the two atriums. The apparently extensive rims of the oval fossa, also described as the septum secundum, or the secondary septum, are largely the infolded walls of the atrial chambers.⁶ This infolding is particularly prominent superiorly, where it forms the extensive fold between the superior caval and right pulmonary veins (Fig. 2-12). This superior interatrial fold is also known as Waterston's, or Sondergaard's, groove. Part of the extensive antero-inferior margin of the oval fossa is unequivocally a septal structure. This is the part formed by muscularisation of the atrial or vestibular spine, also known as the dorsal mesenchymal protrusion. The development of this part of the atrium is discussed extensively, and illustrated, in our chapter devoted to embryology (Chapter 3). Another part is an atrioventricular muscular sandwich, existing because of the more apical attachment of the leaflet of the tricuspid relative to the mitral valve (see below). In this area, an extension of the inferior atrioventricular groove separates the overlapping segments of atrial and ventricular muscle. This area is confluent with the so-called sinus septum, separating the orifices of the coronary sinus and the inferior caval vein (see Fig. 2-11). The sinus septum is no more than the adjacent walls of the two venous structures.

Figure 2-12 This section through the atrial chambers in four-chamber plane shows how the superior rim of the oval fossa, the so-called septum secundum, is simply the infolded walls between the origins of the superior caval vein from the right, and the right pulmonary veins from the left atriums, respectively. Note that the floor of the oval fossa, along with its antero-inferior rim, is a true septal structure interposing between the atrial cavities.

Figure 2-13 As with the right atrium, the morphologically left atrium is made up of an appendage, a venous component, a vestibule and a septal surface. In addition, the left atrium possesses an obvious body, joining together the other parts.

The Morphologically Left Atrium

The left atrium, like its right-sided counterpart, possesses a venous component, an appendage, and a vestibule (Fig. 2-13). Again, in keeping with its morphologically right partner, the morphologically left appendage is the most characteristic and constant component. It is a long tubular structure, usually with several constrictions along its length. Its opening with the venous component is restricted, but its most characteristic feature in malformed hearts is that its pectinate muscles are contained within the appendage, or else they spill only marginally onto the septal surface and the anterior part of the wall we described as the vestibule. The vestibule surrounding the posterior part of the atrioventricular groove, therefore, is smooth. The coronary sinus is located within the atrioventricular groove, and hence is an integral component of the morphologically left atrioventricular junction, even though it opens into the cavity of the morphologically right atrium (Fig. 2-14). Its walls are separate from those of the left atrium itself.⁷ The pulmonary veins open into the corners of the extensive smooth-walled venous component. The septal surface is formed by the flap valve of the oval fossa, which has a characteristically roughened appearance where it overlaps the infolded superior rim (Fig. 2-15). In addition to these parts, the left atrium also possesses a significant body. The evidence for the existence of the body is seen in the setting of totally anomalous pulmonary venous connection. Even when the pulmonary venous component is lacking, there is part of the left atrial chamber that forms a site of union for the appendage, vestibule and septum. This is the body.

Figure 2-14 This cast of the right and left sides of the heart is photographed to show the diaphragmatic surface. The coronary sinus, formed by the union of the great cardiac and oblique veins, is an integral part of the morphologically left atrioventricular junction, but opens into the cavity of the right atrium.

Figure 2-15 In this heart, photographed to show the septal surface of the left atrium, the oval foramen was probe-patent, as shown by the probe placed between the flap valve of the septum and the infolded superior rim.

The Morphologically Right Ventricle

The muscular walls of the right ventricle extend from the discrete atrioventricular junction to their union with the fibroelastic walls of the pulmonary trunk at the anatomical ventriculo-arterial junction. Within the cavity thus demarcated, there are three components, the inlet, the apical trabecular and the outlet parts (Fig. 2-16). The inlet component contains and supports the leaflets of the tricuspid valve, extending to the attachments of the valvar tension

Figure 2-16 The parietal wall of the morphologically right ventricle has been cut away, showing how the ventricular myocardium extends from the atrioventricular (blue dotted line) to the ventriculo-arterial junction (green dotted line). The ventricle itself has inlet, apical trabecular, and outlet components.

Figure 2-17 As seen from their ventricular aspect, the leaflets of the tricuspid valve occupy anterosuperior, inferior and septal positions.

apparatus. The three leaflets of the valve take origin from the septal, inferior or mural, and anterosuperior margins of the atrioventricular junction (Fig. 2-17). The septal leaflet has multiple cordal attachments to the septum. The inferior leaflet runs along the diaphragmatic surface of the ventricle, and its margin with the anterosuperior leaflet is often indistinct. When examined in terms of its pattern of closure, however, there is no doubt about its existence as a third valvar leaflet.⁸ The anterosuperior leaflet is the most extensive of the three, and extends from its zone of apposition with the septal leaflet, an area supported by the medial papillary muscle, to the acute margin of the ventricle. A characteristic anterior papillary muscle arises from the prominent apical trabeculation (see below) to support this leaflet, but not always at its site of apposition with the inferior leaflet.

The apical trabecular part of the ventricle has particularly coarse trabeculations, this being the most constant feature of the ventricle in malformed hearts. One of these trabeculations on the septal surface is particularly prominent, diverging into two limbs at the base to clasp the supraventricular crest. This is the septomarginal trabeculation, or septal band (Fig. 2-18). The medial papillary muscle arises from the posterior limb of this trabeculation, while the anterior papillary muscle springs from the body towards the ventricular apex. The moderator band continues on from the papillary muscle as a discrete muscular bundle, extending to the parietal ventricular wall. A further series of trabeculations extend from the anterior surface of the septomarginal trabeculation and run into the parietal margin of the trabecular zone. These are the septoparietal trabeculations (Fig. 2-19).

The outlet component of the ventricle is relatively smooth walled. It forms the free-standing sleeve of musculature (Fig. 2-20) that supports the leaflets of the pulmonary valve.

Figure 2-18 Opening the right ventricle reveals its muscular roof, the supraventricular crest, which separates the leaflets of the tricuspid and pulmonary valves. The crest inserts to the septum between the limbs of a prominent muscular landmark, the septomarginal trabeculation, or septal band.

Figure 2-19 A series of further muscular structures, the septoparietal trabeculations, arise from the anterior margin of the septomarginal trabeculation, and extend to the parietal wall of the right ventricle. One of these, also extending from the anterior papillary muscle, is the moderator band.

The leaflets of the valve themselves are attached in semilunar fashion within the sleeve, crossing the circular junction between ventricular muscle and the fibroelastic wall of the pulmonary trunk (Fig. 2-21). Because of this arrangement, three crescents of ventricular musculature are incorporated within the bases of the sinuses of the pulmonary trunk, while three triangular areas of pulmonary trunk are incorporated within the ventricular outflow tract beneath the tips of the zones of apposition between the valvar leaflets.⁸ As a result, the valvar leaflets do not possess an annulus in the sense of

Figure 2-20 The pulmonary trunk has been reflected forward relative to the aorta, showing the extensive sleeve of infundibular musculature that lifts the trunk away from the base of the ventricular mass.

Figure 2-21 The pulmonary trunk has been opened, and the valvar leaflets removed from their attachments, revealing the semilunar nature of these attachments. The attachment of each semilunar leaflet crosses the anatomical ventriculo-arterial junction, so that crescents of infundibular musculature are incorporated into the base of each valvar sinus, and triangles of arterial wall are incorporated into the ventricular outflow tract, extending to the level of the sinutubular junction.

a fibrous ring supporting their attachments in circular fashion. Indeed, the most obvious circles within the outflow tract are either the anatomical ventriculo-arterial junction, or else the junction between the valvar sinuses and the tubular pulmonary trunk, the latter best described as the sinutubular junction, and an integral part of the valvar mechanism. There is then another ring that can be constructed by joining together the most proximal parts of the three semilunar leaflets, but this is a virtual structure, with no counterpart (Fig. 2-22). Part of the free-standing subpulmonary infundibular sleeve interposes between the leaflets of the pulmonary and tricuspid valves. This is the supraventricular crest (see Fig. 2-18). It is often illustrated as representing a septal structure. In reality, as can be shown by removing the wall (Fig. 2-23), it is largely made up from the inner curvature of the right ventricular musculature. We describe this

Figure 2-22 The cartoon represents the anatomy as depicted in Figure 2-21. The true rings, or annuluses, are the line over which the walls of the pulmonary trunk join the muscular infundibulum, or the anatomical ventriculo-arterial junction, depicted in *yellow*, and the sinutubular junction, shown in *blue*. A third ring can be constructed by joining together the basal attachments of the valvar leaflets, as shown in *yellow*. The *red lines* show the semilunar attachments of the valvar leaflets.

Figure 2-23 The dissection shows that the greater part of the supraventricular crest is made up of the parietal ventricular wall. As can be seen, removing this wall reveals the sinuses of the aorta.

area as the ventriculo-infundibular fold. It is also the case that a small part of the musculature between the limbs of the septomarginal trabeculation can be removed to provide access to the left ventricle, this small part truly representing a muscular outlet septum (Fig. 2-24). The outlet part, however, cannot be distinguished in normal hearts from the remainder of the muscular ventricular septum. The key feature of the infundibular area, therefore, is the sleeve of free-standing musculature that supports the leaflets of the

Figure 2-24 The dissection shown in Figure 2-23 has been continued, showing that it is possible to remove a very small part of the septum, immediately between the limbs of the septomarginal trabeculation, so as to gain access to the left ventricle. This small part, representing a true muscular outlet septum, cannot be distinguished from the remainder of the septum without the aid of dissection.

pulmonary valve, the presence of this sleeve making it possible surgically to remove the valve as an autograft in the Ross procedure.⁸⁻¹⁰

The Morphologically Left Ventricle

The inlet, apical trabecular and outlet components of the left ventricle (Fig. 2-25) are as distinct as their counterparts within the right ventricle, and each shows significant features permitting its recognition. The inlet component surrounds and supports the leaflets of the mitral valve and its paired papillary muscles. The components of the valve are best distinguished in closed rather than open position. When the valve is viewed with the leaflets adjacent to one another, the

Figure 2-25 As with the morphologically right ventricle (see Fig. 2-15), the morphologically left ventricle can readily be described in terms of its inlet, apical trabecular and outlet components.

Figure 2-26 When viewed in its closed position, it can be seen that a solitary concave zone of apposition separates the leaflets of the mitral valve. The zone of apposition does not reach to the annular attachments of the leaflets. Note the slits in the mural leaflet, necessary to permit the two leaflets to close snugly.

solitary line of apposition is readily apparent (Fig. 2-26). In terms of valvar function, this zone of apposition represents the commissure between the leaflets. The mitral valve would best be described, therefore, as having one commissure. Almost always, however, the valve is illustrated in open position, and then it is the ends of the zone of apposition that are usually interpreted as the paired commissures, and typically described as being postero-medial and antero-lateral. This convention introduces major complications. Those who analyze the valve in open, rather than closed, position point to the characteristic fan-shaped pattern of branching of the tendinous cords at the ends of the zone of apposition.¹¹ With the passage of time, these fan-shaped structures have, by convention, become recognised as commissural cords. Similar fan-shaped ramifications, nonetheless, are found supporting the slits in the extensive mural leaflet of the valve, particularly between those well-formed components that are often identified as the scallops. Because of the resemblance of these areas to the ends of the major zone of apposition, some suggest that the valve is better viewed as possessing four leaflets.¹² The valvar architecture, however, is not sufficiently constant to support this notion, which is avoided when the leaflets of the valves are assessed in terms of their closed position. The valvar leaflets can then simply be recognised on the basis of the obvious solitary zone of apposition between them. Such inspection shows that the mural, or posterior, leaflet is a lengthy, albeit shallow, structure that guards two-thirds of the overall valvar circumference, with several slits along its length, which permit it to fit snugly against the other aortic or anterior leaflet.¹³ The major feature of this other leaflet is its fibrous continuity, on its ventricular aspect, with parts of the left coronary and non-coronary leaflets of the aortic valve, hence our preferred title of the aortic leaflet. It is much deeper than the mural leaflet, but guards only one-third of the valvar circumference. The tendinous cords from the leaflets insert mostly to the paired papillary muscles, which are seated adjacent to one another on the parietal wall of the ventricle. When viewed in attitudinally appropriate position, however, they are located supero-anteriorly and infero-posteriorly (Fig. 2-27), rather than postero-medially and antero-laterally.¹⁴ The latter descriptions hold good only when the heart is removed

Figure 2-27 The posterior wall of the left ventricle has been removed, and the heart is photographed from behind. The dissection reveals the relations of the two papillary muscles of the mitral valve, which are positioned supero-posteriorly and infero-anteriorly.

from the body and positioned on its apex. The oft-illustrated spread position of the leaflets is also artefactual, reflecting the way in which the ventricle has been opened.

Many anatomists have used complex systems to describe the tendinous cords that support the leaflets of the atrio-ventricular valves. Such categorisation is not very helpful. Suffice it to say that, in the normal heart, cords arise uniformly along the free leading edge of all the valvar leaflets, and extend to insert into the supporting papillary muscles. Each papillary muscle supports the adjacent parts of two leaflets. These cords providing uniform support to the free edges of the leaflets are then reinforced by the prominent strut cords found on the ventricular aspect of the aortic leaflet, and by basal cords that run from the undersurface of the mural leaflet to insert directly into the myocardium. Unlike the tricuspid valve, the mitral valve has no cords inserting directly into the ventricular septum. Instead, the deep subaortic outflow tract separates the aortic leaflet of the valve from the smooth septal surface of the left ventricle (Fig. 2-28).

Figure 2-28 The short axis of the ventricular mass is shown as seen from the apex. Note the extensive diverticulum created by the subaortic outflow tract, which separates the mitral valve from the septum. Note also that, unlike the tricuspid valve, the leaflets of the mitral valve, best described as aortic and mural, have no direct cordal attachments to the septum.

Figure 2-29 The aorta has been opened through the area of aortic-to-mitral valvar continuity, and is viewed from behind, the leaflets of the valve having been removed. Note that, as with the pulmonary valve (see Fig. 2-21), the leaflets are attached within the aortic root in semilunar fashion, so that fibrous triangles of aortic wall are incorporated within the ventricular outflow tract, and segments of ventricular musculature within the bases of the two coronary arterial sinuses.

The trabecular component of the left ventricle extends beyond the papillary muscles of the mitral valve, reaching to the relatively thin apical point. The trabeculations themselves are significantly finer than those of the right ventricle, and criss-cross in characteristic fashion (see Fig. 2-25). Strands often cross the cavity of the ventricle, particularly from the papillary muscles, in the fashion of telephone wires. They are of no functional significance. The surface of the septal aspect of the trabecular component is smooth, with no evidence of any structure comparable to the septomarginal trabeculation of the right ventricle. The left bundle branch descends from the crest of the muscular ventricular septum and fans out in this area.

The outlet component is significantly abbreviated in comparison to its right ventricular counterpart, with the leaflets of the aortic valve supported by musculature only around the anterior quadrants of the outflow tract (see Fig. 2-28). Posteriorly, two of the leaflets of the aortic valve are in fibrous continuity with the deep aortic leaflet of the mitral valve. Despite this difference in terms of support, the overall semilunar structure of the aortic valve is comparable to that of the pulmonary valve (Fig. 2-29). As in the right ventricle (see Fig. 2-22), the semilunar attachments incorporate crescents of ventricle within the bases of the three aortic sinuses of Valsalva, while three triangles of arterial wall are incorporated within the outflow tract beneath the apices of the zones of apposition between the valvar leaflets.

The location of these three fibrous triangles separating the zones of apposition of the leaflets helps in understanding the relationships of the aortic valve.¹⁵ The leaflets of the valve itself are named according to the origin of the coronary arteries from the aortic sinuses. Thus, the sinuses, and the leaflets they support, can be distinguished as being left coronary, right coronary, and non-facing. Non-facing is preferable to non-coronary (Fig. 2-30) because, very rarely, the so-called non-coronary sinus can give origin to a coronary artery. In such a setting, the non-coronary title would obviously become nonsensical. Non-facing is also a good term because, without exception, and irrespective of

Figure 2-30 This dissection of the short axis of the heart, shown from its atrial aspect, shows how the coronary sinuses, and the leaflets of the aortic valve, can be described as right coronary, left coronary and non-facing. In almost all instances the non-facing sinus does not give rise to a coronary artery, so it can also be described as the non-coronary sinus.

the relationships of the arterial trunks, two of the aortic sinuses face, or are adjacent to, corresponding sinuses of the pulmonary trunk. This permits the sinuses of the pulmonary trunk similarly to be distinguished as right-facing, left-facing, and non-facing, or non-adjacent.

The fibrous triangle that separates the left coronary leaflet from the non-facing leaflet of the aortic valve separates the left ventricular outflow tract from the transverse sinus of the pericardium, forming the wall between the back of the aorta and the anterior interatrial groove (Fig. 2-31). The triangle separating the right coronary aortic leaflet from the non-coronary leaflet is directly continuous with the membranous septum. When the triangle is removed, it can be seen to separate the left ventricular outflow tract from the transverse sinus above the inner curvature of the right ventricle, specifically with the pericardial space above the supra-ventricular crest (Fig. 2-32). The triangle which separates the two coronary leaflets of the aortic valve separates the cavity of the left ventricle from the tissue interposing between the anterior surface of the aorta and the posterior surface of the free-standing subpulmonary infundibulum (Fig. 2-33).

The Arterial Trunks

The two great arteries leave the base of the heart at the ventriculo-arterial junctions, extending superiorly into the mediastinum, with the pulmonary trunk spiralling around the centrally located aorta as it bifurcates. Its branches then extend to the hilums of the lungs. Each arterial trunk shows a characteristic cloverleaf shape at its root, with the truncal sinuses interdigitating with the supporting ventricular structures as they support the arterial valvar leaflets in semilunar fashion (Fig. 2-34). There is then a characteristic ring-like

Figure 2-31 The aortic root has been opened by a cut made between the non-facing and left coronary aortic sinuses. The cut transects the fibrous interleaflet triangle, showing how this area interposes between the left ventricular outflow tract and the transverse sinus of the pericardium.

Figure 2-33 This long-axis section, paralleling the parasternal long-axis echocardiographic plane, is made between the two arterial sinuses of the aortic valve. It shows how the fibrous interleaflet triangle between these sinuses separates the left ventricular outflow tract from the fibrofatty tissue plane between the aortic wall and the free-standing subpulmonary muscular infundibulum.

Figure 2-32 The heart is shown from the right side, the interleaflet triangle between the non-facing and right coronary aortic sinuses having been removed. Note how the top of the triangle separates the left ventricular outflow tract from the transverse sinus of the pericardium (yellow star), which lines the epicardial aspect of the supraventricular crest.

Figure 2-34 The aortic root is viewed from above, having transected the aorta. Note how the zones of apposition between the leaflets of the aortic valve close snugly along lines from the centre of the valvar orifice (red stars) to the attachments at the sinutubular junction (yellow star), making the latter attachments an integral part of the valvar complex.

junction to be found between the expanded sinuses and the tubular trunk of each great artery. The tips of the zones of apposition between the arterial valvar leaflets, usually known as the commissures, are firmly attached to this sinutubular junction, thus making it an integral part of the valvar complex. Stenosis occurring at this level, therefore, is valvar rather than supravalar. The arrangement of the closed valve also

show that the entirety of the zones of apposition between the leaflets should be considered to represent the commissures, rather than merely their peripheral attachments.

The pulmonary trunk runs only a short course before bifurcating into the right and left pulmonary arteries, which then extend to the respective lung hilums. The aorta continues through its ascending component above the sinutubular

Figure 2-35 The intrapericardial arterial trunks spiral round one another as they extend from the base of the heart. The aorta, having exited the pericardial cavity, gives rise to the brachiocephalic (BCA), left common carotid (LCA) and left subclavian (LSCA) arteries. Note the arterial duct extending from the left pulmonary artery to the underside of the aortic arch, delimiting the distal end of the aortic isthmus (double-headed arrow). Desc., descending; Pulm., pulmonary.

junction until it runs horizontally as the transverse arch, giving rise to the brachiocephalic, left common carotid and left subclavian arteries (Fig. 2-35). The zone between the origins of the left subclavian artery and the arterial ligament, or the junction with the arterial duct prior to closure of this structure, is known as the isthmus. Beyond this point, the arch becomes the descending thoracic aorta. The arterial duct, or ligament after its closure, runs from the underside of the arch to the upper surface of the left pulmonary artery. The left recurrent laryngeal nerve turns back into the mediastinum round the duct or its ligamentous remnant.

THE VALVES OF THE HEART

Although we have already discussed the morphological features of the atrioventricular and arterial valves, these are such significant structures in normal and abnormal function of the heart that it is worthwhile reviewing the component parts of each set of valves, and the terms we use to describe them.

The Atrioventricular Valves

The atrioventricular valves guard the inlets to the ventricular mass and, as such, have to withstand the full force of ventricular contraction when in their closed position. For this reason, it is better to examine the valves in their closed position, taking care, of course, also to take note of their features when open. The overall valvar complex is made up of the annulus, the leaflets, the tension apparatus, and the papillary muscles. The annulus is a much firmer structure in the mitral than in the tricuspid valve. Even in the mitral valve, it is unusual to find a complete collagenous structure supporting the leaflets. In the tricuspid valve, it is the rule

for the valvar leaflets to be suspended from the endocardial surface of the atrioventricular junction, with the fibrofatty tissue of the atrioventricular groove serving to insulate electrically the atrial from the ventricular musculature.

We distinguish the leaflets of the valves by determining the fashion in which they fit together in closed position. In this way, it can readily be seen that the mitral valve has two leaflets,¹⁴ while the tricuspid valve has three.⁸ This, of course, is no more than a restatement of well-established anatomical fact. It is the zones of apposition that are the key structures in defining the extent of the leaflets. This approach, focusing on zones of apposition, works for arterial as well as atrioventricular valves and is as useful for the valves seen in congenitally malformed as in otherwise normal hearts. We have already discussed, when describing the mitral valve, the different types of tendinous cord and the complicated categorisations that some use to describe them. In simple terms, the cords can be divided into those originating from the free edges of the leaflets and those coming from the ventricular aspects, the latter being divided into strut and basal cords.¹⁴ Distinguishing the leaflets according to their patterns of closure avoids the need to subdivide the cords from the free edge of the leaflets into commissural or cleft variants.^{8,15} This, in turn, avoids the controversies that arise in attempting to make these difficult distinctions. In the normal heart, the entire leading edges of the leaflets are uniformly supported by tendinous cords, the key feature being that the edges of adjacent leaflets at the peripheral ends of the zones of apposition are tethered to the same papillary muscle. It is also of note that, at the ends of the zones of apposition, there is a curtain of valvar tissue separating the valvar orifice from the annulus (see Fig. 2-26).

The papillary muscles of the valves are distinctive structures. The tricuspid valve is supported by a small medial muscle that arises from the posterior limb of the septomarginal trabeculation, a prominent anterior muscle, and an inferior muscle, the last named often duplicated or triplicated. The septal leaflet of the valve is characterised by its multiple direct cordal attachments to the septum. The mitral valve, in contrast, has obviously paired papillary muscles located infero-anteriorly and supero-posteriorly within the ventricular cavity, albeit that the heads of both muscles are frequently multiple. Each muscle supports the adjacent ends of the aortic and mural leaflets of the valve, being positioned beneath the two ends of the solitary zone of apposition between the leaflets.

The Arterial Valves

As with the atrioventricular valves, we view the outlet valves of the ventricular mass as complex structures with multiple components, these being the supporting ventricular walls, the leaflets, the sinuses, the interleaflet triangles, and the sinutubular junction. As such, each arterial valve extends from the basal attachment of the leaflets to the ventricular walls to the peripheral attachments of the zones of apposition between adjacent leaflets at the sinutubular junction. Within this valvar complex, most will continue to seek the annulus or ring. In reality, the entire valvar complex is a ring, or crown, and there is no cord-like collagenous circle within the valvar structure that supports the semilunar attachments of the leaflets.¹⁶ At least three zones within the complex can justifiably be described as rings (see Fig. 2-22). The first is the

sinutubular junction. The second is the anatomical ventriculo-arterial junction, this being the circular area over which the fibroelastic wall of the arterial trunk joins with the supporting ventricular walls. This anatomical junction should be distinguished from the haemodynamic boundary between ventricle and arterial trunk, this being marked self-evidently by the semilunar attachment of the valvar leaflets.¹⁷ We have already emphasised how, in both aortic (see Fig. 2-29) and pulmonary (see Fig. 2-21) valves, this arrangement results in crescents of ventricular wall being incorporated within the truncal sinuses, and triangles of arterial wall being incorporated within the ventricular outflow tracts (see Fig. 2-22). The final ring within the valvar complex is an incomplete circle, formed by joining the basal attachments of the leaflets within the ventricles. The reason that some surgeons describe a semilunar annulus is surely because, having removed the leaflets of a diseased valve, they see the semilunar remnants, which they use as points of anchorage for the sutures that secure in place the prostheses used as valvar replacements.

The Septal Structures

Although each of the septal structures has already been described, it is worth re-emphasising their structure, the more so since only cursory mention has been made of the important membranous part of the ventricular septum. In this respect, only those parts of the cardiac walls that separate adjacent chambers should be described as septal.¹⁸ Walls that separate the cavity of a chamber from the outside of the heart, even when folded on themselves, are not part of the septal structures.

The atrial septum, when defined in this fashion, is composed primarily of the floor of the oval fossa, this being the flap valve. In addition to the floor, only the antero-inferior rim of the fossa is a true septum in its own right, since the other margins are the infolded atrial walls, or else the atrial wall overlapping the base of the ventricular mass (see Fig. 2-12). The so-called sinus septum is no more than the branching point of the coronary sinus and the inferior caval vein.

Contiguous with both sinus septum and the inferior margin of the oval fossa is the area known as the triangle of Koch (Fig. 2-36). This important zone is the atrial aspect of an atrioventricular muscular sandwich, made up of overlapping areas of atrial and ventricular myocardium, the two separated by a fibrofatty extension from the inferior atrioventricular groove. In this area, as shown by the so-called four-chamber section, the leaflets of the tricuspid valve are attached more apically than are those of the mitral valve (Fig. 2-37). The apex of the triangle of Koch is made up of the fibrous tissue in the posterior component of the aortic root. Within this tissue is incorporated the fibrous part of the atrioventricular septum, itself a part of the membranous septum of the heart (Fig. 2-38). This is the only true atrioventricular septum. Taken overall, the membranous septum is contiguous with the fibrous triangle beneath the zone of apposition between the non-coronary and the right coronary leaflets of the aortic valve (see Fig. 2-32). It is the line of attachment of the tricuspid valve on its right aspect that divides the membranous septum into its atrioventricular and interventricular components, albeit that the proportions of the two components vary markedly from heart to heart.

The interventricular component of the membranous septum, when considered relative to the bulk of the muscular

Figure 2-36 This picture shows how tension on the Eustachian valve brings into prominence the tendon of Todaro, which together with the line of attachment of the septal leaflet of the tricuspid valve forms the boundaries of the triangle of Koch. Note that the patient also has a large defect in the floor of the oval fossa. (Courtesy of Dr Benson R. Wilcox, University of North Carolina, Chapel Hill.)

Figure 2-37 The heart has been sectioned in four-chamber plane, showing the sandwich formed by the atrial myocardium and the crest of the muscular ventricular septum (star) between the off-set attachments of the leaflets of the tricuspid and mitral valves (arrows).

ventricular septum, is inconspicuous, but forms the key-stone of the septum within the aortic root. We thought, in the past, that we were able to divide the much larger muscular ventricular septum into inlet, apical trabecular, and outlet components, thinking that these septal components matched the corresponding parts of the ventricular cavities.¹⁹ In reality, the parts of the septum separating the inlet and

Figure 2-38 This heart has also been sectioned in four-chamber plane, but anteriorly relative to the cut shown in Figure 2-37. This cut, taken through the membranous septum, shows how the fibrous part of the septum (bracket) is divided into atrioventricular (red arrow) and interventricular (yellow arrow) components by the attachment of the septal leaflet of the tricuspid valve. (Courtesy of Dr Sandra Webb, St. George's Medical University, London, United Kingdom.)

outlet of the right ventricle from their comparable components in the left ventricle are not nearly so large as was initially thought. Because of the deeply wedged location of the subaortic outlet component, much of the septum supporting the septal leaflet of the tricuspid valve separates the inlet of the right ventricle from the left ventricular outlet (Fig. 2-39). In addition, because of the free-standing nature of

Figure 2-39 This four-chamber section is also taken through the aortic root (compare with Figs. 2-37 and 2-38). It shows how the inlet part of the muscular septum, because of the wedged location of the subaortic outflow tract (arrow) separates the inlet of the right ventricle from the left ventricular outlet. It is, in reality, an inlet-outlet septum.

the subpulmonary infundibulum, only a very small part of the muscular septum is a true outlet septum (see Fig. 2-24). In the normal heart, therefore, there are no obvious boundaries that divide the muscular ventricular septum into its component parts. The outlet septum seen as an anatomical entity achieves a separate existence only when the septum itself is deficient, particularly when this part is malaligned relative to the rest of the muscular septum.

THE FIBROUS SKELETON

Many textbooks illustrate the basal section of the heart as seen in the short axis containing a fibrous skeleton that embraces the origins of, and provides the attachments for, the leaflets of all four cardiac valves. There is no foundation in anatomical fact to support this notion. As already shown, the leaflets of the pulmonary valve are supported on an extensive sleeve of free-standing right ventricular musculature (see Figs. 2-20 and 2-21). Endorsing the findings of McAlpine,²⁰ we have been unable to identify the so-called tendon of the conus, or infundibular ligament.²¹ The leaflets of the aortic valve also arise in part from the septal musculature and in part from a zone of fibrous continuity with the aortic leaflet of the mitral valve (see Fig. 2-29). It is this zone of fibrous continuity that forms the basis of the cardiac skeleton. The two ends of the zone are thickened to form the right and left fibrous trigones (Fig. 2-40). The right fibrous trigone is then continuous with the membranous septum, the conjoined structure being known as the central fibrous body. This is the strongest part of the fibrous skeleton. From the two fibrous trigones, cords of fibrous tissue extend around the orifices of the mitral valve. It is rare, however, to find these cords encircling the entirety of the valvar orifice, and providing uniform support for

Figure 2-40 It is the right and left fibrous trigones, the thickenings at the ends of the zone of fibrous continuity between the leaflets of the aortic and mitral valves (dotted line), together with the membranous septum, that form the basis of the fibrous skeleton of the heart. Note that the right fibrous trigone joins with the membranous septum to form the so-called central fibrous body. The atrioventricular bundle penetrates through this part of the heart.

the attachments of mural leaflet of the mitral valve. The fibrous tissue can be well formed around the mitral valve, but frequently takes the form of a short fibrous strip, rather than a circular cord.²² Often, the fibrous tissue fades out completely at various sites around the ring, with the atrial and ventricular muscle masses being separated one from the other by fibrofatty tissue of the atrioventricular groove in these locations. The mitral valvar leaflets then take origin from the ventricular myocardium, rather than from a fibrous skeleton. This arrangement is the rule rather than the exception in the right atrioventricular junction, where it is usually the fibrofatty tissues of the atrioventricular groove that serve to insulate the atrial from the ventricular musculature. Taken together, therefore, the fibrous skeleton of the human heart is relatively poorly formed, being a firm structure only within the aortic root.²³

THE CONDUCTION TISSUES

The conduction tissues are small areas of specialised myocardium that originate and disseminate the cardiac impulse. Although it is only rarely possible to visualise the tissues directly, their sites are sufficiently constant for accurate anatomical landmarks to be established as a guide to their location.

The cardiac impulse is generated in the sinus node.²⁴ This small cigar-shaped structure is located, in a majority of individuals, subepicardially within the terminal groove, being positioned inferior to the crest of the atrial appendage (Fig. 2-41). In about one-tenth of individuals, however, the node extends across the crest of the appendage to sit like a horseshoe, with one limb in the terminal groove, and the other in the interatrial groove (see Fig. 2-41, inset). Equally

important to the location of the node is the course of its arterial supply. The artery to the sinus node is the most prominent atrial artery. It arises in most individuals from the initial course of either the right or the circumflex coronary artery. It then runs through the interatrial groove, and enters the terminal groove across or behind the cavoatrial junction, with an arterial circle formed in a minority of individuals. In some individuals, the artery arises from the lateral part of the right coronary artery, or else from the distal course of the circumflex artery. The nodal artery then runs either across the lateral margin of the right atrial appendage or across the dome of the left atrium.²⁵ In either event, it can be at major risk when a surgeon makes a standard incision to enter the atrial chambers.

The impulse from the sinus node is conducted at the nodal margins into working atrial myocardium, and it is then carried through the working myocardium towards the atrioventricular node. Much has been written in the past concerning the presence of so-called internodal atrial tracts. Anatomical studies show that there are no narrow and insulated tracts of cells that join the cells of the sinus node to those of the atrioventricular node that are, in any way, analogous to the insulated ventricular conduction pathways (see below). There may be pathways of preferential conduction through the terminal crest and the sinus septum and around the margins of the oval fossa. The more rapid spread of conduction through these areas is simply a consequence of the more ordered packing of the myocardial fibres within these prominent muscular bundles (Fig. 2-42).

The atrioventricular node,²⁶ surrounded on most sides by short zones of transitional cells, is contained exclusively within the triangle of Koch. This important landmark is delineated by the tendon of Todaro, the attachment of the

Figure 2-41 The cartoon shows the location of the sinus node, which lies immediately subepicardially within the terminal groove. In a minority of patients it occupies a horseshoe position (*inset*). IVC, inferior caval vein; SCV, superior caval vein.

Figure 2-42 Removal of the epicardium shows well the parallel arrangement of the muscular fibres in the prominent bundles of the right atrium. It is this orderly arrangement that is responsible for the preferential nature of internodal conduction. Note also the continuation of the Eustachian valve as the tendon of Todaro. Together with the hinge of the septal leaflet of the tricuspid valve (*dotted lines*), the tendon delineates the triangle of Koch. The atrioventricular node is situated at the apex of this triangle (*star*). (Courtesy of Professor Damian Sanchez-Quintana, University of Badajoz, Spain.)

Figure 2-43 The section is taken through the junction of the atrial and ventricular septums, and is orientated attitudinally, with the right atrium uppermost. Note the cells of compact atrioventricular (AV) node set as a half-oval against the insulating fibrous tissue of the central fibrous body, with transitional cells interposing on most sides between the cells of the node and the atrial myocardium.

septal leaflet of the tricuspid valve and the orifice of the coronary sinus (see Figs. 2-36 and 2-42). The specialised myocardial cells of the node, and the transitional zones, are situated within the atrial component of the atrioventricular muscular septum,²⁷ with the atrial myocardium approaching the node from all sides (Fig. 2-43). The floor of the coronary sinus in this area roofs the inferior pyramidal space. This space is paraseptal,²⁸ situated between the atrial musculature and the crest of the muscular ventricular septum (Fig. 2-44). The artery to the atrioventricular node courses anteriorly through this space into the triangle of Koch (see Fig. 2-37), having taken origin from the dominant coronary artery (see below).

From the apex of the triangle of Koch, it is but a short distance for the atrioventricular conduction axis to penetrate the central fibrous body as the bundle of His, better described as the penetrating atrioventricular bundle. Having penetrated, the bundle reaches the crest of the muscular septum beneath the non-facing leaflet of the aortic valve (Fig. 2-45), where it branches. The left bundle branch then runs down the smooth left surface of the septum, before fanning out towards the ventricular apex (see Fig. 2-45). The right bundle branch traverses the septum to emerge beneath the medial papillary muscle. It then extends as a thin insulated cord in the substance of the septomarginal trabeculation before ramifying at the ventricular apex. A prominent branch usually passes to the parietal wall through the moderator band.

BLOOD SUPPLY TO THE HEART

The Coronary Arteries

The coronary arteries are the first branches of the aorta, usually taking their origin within the bulbous expansions of the aortic root proximal to the sinutubular junction known

Figure 2-44 Removing the floor of the coronary sinus reveals the pyramidal space between the atrial musculature and the diverging infero-posterior margins of the ventricular walls. This space, containing the artery to the atrioventricular node, is a superior extension from the inferior atrioventricular groove.

Figure 2-45 The figure shown is Figure 1 from Table 6 of the monumental monograph published by Sunao Tawara in 1906. It shows, in dotted lines, the location of the knot (k), or atrioventricular node, and the penetrating atrioventricular bundle. The reconstruction shows, in red, the location of the trifascicular left bundle branch on the surface of the ventricular septum. Removal of the non-coronary sinus of the aorta reveals the very short distance needed to be traversed by the penetrating atrioventricular bundle (of His) as it passes from the apex of the triangle of Koch (bullet) to reach the crest of the muscular ventricular septum.

as the aortic sinuses of Valsalva. As already discussed, there are two major coronary arteries and three aortic sinuses (see Fig. 2-30). Almost without exception, the arteries arise from one or the other of the sinuses closest to the pulmonary trunk, these being the adjacent or facing sinuses. In most normal individuals, one artery arises from each of these facing sinuses, permitting them to be named the right coronary and left coronary sinuses, respectively (see Fig. 2-30). It is useful, nonetheless, to have a convention for naming the sinuses that works irrespective of the origin of the coronary arteries, and irrespective of the relationship

Figure 2-46 When an observer views the aortic sinuses from the non-facing sinus looking towards the pulmonary trunk, then, irrespective of the relationship of the great arteries, one aortic sinus is always to the left hand and the other to the right hand. In the normal situation, the sinus to the right hand, known as #1, gives rise to the right coronary artery, while the sinus to the left hand, known as #2, gives rise to the main stem of the left coronary artery.

of the aorta to the pulmonary trunk. This is provided by observing the aortic sinuses from the point of the non-facing sinus, and looking towards the pulmonary trunk (Fig. 2-46). One facing sinus is then to the right hand of the observer, and this is the sinus that usually gives rise to the right coronary artery. The other sinus is to the left hand of the observer, and usually gives rise to the main stem of the left coronary artery. By convention, the facing sinus to the right hand has become known as sinus 1, while the left hand facing sinus is known as sinus 2.²⁹ As we will see, this convention, known as the Leiden Convention, holds good for naming the aortic sinuses and the origin of the coronary arteries, even when the arterial trunks are abnormally disposed in congenitally malformed hearts.

In the normal heart, it is the right coronary artery that arises from the right hand facing sinus, usually but not always beneath the sinutubular junction, and oftentimes eccentrically positioned within the sinus. It is by no means uncommon for additional arteries to arise directly within the sinus, most frequently the infundibular artery or the artery to the sinus node. The right coronary artery itself passes directly into the right atrioventricular groove, lying in the curve of the ventriculo-infundibular fold above the supraventricular crest (Fig. 2-47). From this initial course, the artery gives rise to infundibular and atrial branches before turning round the acute margin of the ventricular mass, where it gives rise to the acute marginal origin. The main stem of the right coronary artery then continues along the diaphragmatic surface of the right atrioventricular junction, giving off additional atrial and ventricular branches until, in about nine-tenths of individuals, it gives rise to the inferior interventricular artery, described as being posterior in most current textbooks, but unequivocally positioned inferiorly when the heart is located within the chest. The right coronary artery usually continues beyond the crux to supply a variable portion of the diaphragmatic surface of the left ventricle. This arrangement is called right coronary arterial dominance.

The main stem of the left coronary artery, having taken origin from the left hand facing sinus, passes into the left

Figure 2-47 The dissection shows the course of the right coronary artery. Having arisen from its aortic sinus, the artery encircles the right atrioventricular junction, giving off atrial and ventricular branches. In nine-tenths of individuals, as in this instance, it gives rise to the inferior interventricular artery, continuing beyond the crux to supply the diaphragmatic walls of the left ventricle.

Figure 2-48 The main stem of the left coronary, having emerged from the aortic sinus, branches immediately into its anterior interventricular and circumflex branches.

atrioventricular groove beneath the orifice of the left atrial appendage. It then immediately branches into the anterior interventricular and circumflex arteries (Fig. 2-48). In some individuals a third artery, the intermediate artery, supplies directly the obtuse marginal surface of the left ventricle. It is much rarer for additional arteries to arise within the left

Figure 2-49 Removal of the free-standing subpulmonary infundibulum shows well the origin of the right and left coronary arteries from the aorta. Note the origin of the first septal perforating artery from the anterior interventricular artery.

hand facing sinus, but sometimes the two major arteries have independent origins. More usually, albeit still rarely, it is the sinus nodal artery that takes a separate origin from this sinus. The anterior interventricular artery, also known as the anterior descending artery, runs down the anterior interventricular groove, giving diagonal branches to the adjacent surfaces of the right and left ventricles, along with the perforating arteries, which pass perpendicularly into the ventricular septum. The first septal perforating branch is particularly significant, being located immediately posterior to the free-standing sleeve of subpulmonary infundibular musculature (Fig. 2-49). The extent of the circumflex artery depends on whether the right coronary artery is dominant. When the right artery is dominant, then the circumflex artery often terminates abruptly after it has given rise to the obtuse marginal branch or branches. Sometimes, in perhaps one-tenth of individuals, the circumflex artery is dominant. It then runs all the way round the left atrioventricular junction and continues beyond the crux to supply part of the diaphragmatic surface of the right ventricle, as well as giving rise to the inferior interventricular artery and the artery to the atrioventricular node (Fig. 2-50).

The Coronary Veins

The venous return from the heart is, for the most part, collected by the major cardiac veins, which run alongside the coronary arteries in the interventricular and atrioventricular grooves. The largest vein, termed the great cardiac vein, accompanies the anterior interventricular artery, turning beneath the left atrial appendage to join the coronary sinus. The junction between vein and sinus is the point of entrance of the oblique vein of the left atrium, or the vein of Marshall, which usually corresponds with the site of a prominent venous valve, the valve of Vieussens.

Figure 2-50 In this heart, the circumflex artery, running within the postero-inferior left atrioventricular groove, continues beyond the crux of the heart, where it gives rise to the inferior interventricular artery and the artery to the atrioventricular node.

The coronary sinus then runs within the left atrioventricular groove to the right atrium (Fig. 2-51). As it enters the right atrium, it collects the middle cardiac vein, which accompanies the inferior interventricular artery, and the small cardiac vein, which runs in the right atrioventricular groove. Further smaller veins usually drain into the sinus as it courses within the left atrioventricular groove. When there is a persistent left superior caval vein, it usually drains into the coronary sinus along the route normally occupied by the oblique vein. An additional series of veins, the minor cardiac veins, usually three to four in number, drain the blood from the anterior surface of the right ventricle

Figure 2-51 The cartoon, showing the heart viewed from behind, illustrates the arrangement of the coronary veins.

and enter directly the infundibulum. A further series of minimal cardiac veins, or Thebesian veins, then drain the blood from the walls of the right and left atriums, opening directly into the atrial cavities.

ANNOTATED REFERENCES

- Cook AC, Anderson RH: Attitudinally correct nomenclature [editorial]. *Heart* 2002;87:503–506.

Although we had indicated that, having studied the book of McAlpine, we also would use anatomically appropriate nomenclature, for a long time we failed to follow our own advice. In this editorial, we stressed again the importance of adopting the suggestions of McAlpine.

- Anderson RH, Brown NA, Webb S: Development and structure of the atrial septum. *Heart* 2002;88:104–110.

In this review, we emphasised the difference between the true atrial septum, formed largely by the flap valve, which can be removed without creating a communication with the extracardiac spaces, as opposed to the so-called septum secundum, in reality the superior interatrial groove. It is possible to pass between the atrial chambers by cutting through this fold, but only by, at the same time, transgressing on the extracardiac space.

- Chauvin M, Shah DC, Haissaguerre M, et al: The anatomic basis of connections between the coronary sinus musculature and the left atrium in humans. *Circulation* 2000;101:647–652.

In this study, the French group showed that the coronary sinus and the left atrium each possess their own walls. Prior to this investigation, it had been presumed that a common wall interposed between the cavities of the venous structure and the atrium.

- Merrick AF, Yacoub MH, Ho SY, Anderson RH: Anatomy of the muscular subpulmonary infundibulum with regard to the Ross procedure. *Ann Thorac Surg* 2000;69:556–561.

We pointed out that, unless the pulmonary valve was truly supported by its muscular infundibular sleeve, it would be impossible to remove the valve for use as an autograft in the Ross procedure. The corollary of this finding is that there is no outlet septum interposed between the back wall of the right ventricular outflow tract and the aortic valvar sinuses.

- Victor S, Nayak VM: Definition and function of commissures, slits and scallops of the mitral valve: Analysis in 100 hearts. *Asia Pacific J Thorac Cardiovasc Surg* 1994;3:10–16.

In this work, the authors pointed out that examining the mitral valve in its closed position negated the need to define commissures on the basis of the arrangement of the tendinous cords. When the valve is seen in its closed position, it is obvious that there is but a solitary line of closure for the mitral valve, albeit that the mural leaflet has multiple slits along its length to permit competent closure.

- Sutton JP III, Ho SY, Anderson RH: The forgotten interleaflet triangles: A review of the surgical anatomy of the aortic valve. *Ann Thorac Surg* 1995;59:419–427.

In this investigation, we showed that, because of the semilunar nature of the attachments of the arterial valvar leaflets, crescents of ventricle were incorporated into the bases of the arterial sinuses, whilst triangles of fibrous tissue extended to the sinutubular junction as parts of the ventricle. We also emphasised that, because of these anatomical arrangements, the arterial valves did not possess an annulus in terms of a circular structure supporting the leaflets in cord-like fashion. Instead, the arrangement resembled a crown.

In this review, celebrating the centenary of discovery of the sinus node by Keith and Flack, we review the history of the discovery and put the anatomic findings into the context of the subsequent researches into electrophysiology and developmental biology.

- Tawara S: *Das Reizleitungssystem des Säugetierherzens.* Jena: Gustav Fischer, 1906.

In this monumental monograph, Tawara clarified the arrangement of the specialised muscular axis responsible for atrioventricular conduction, demonstrating for the first time the existence of the atrioventricular node. As was emphasised by Keith in his autobiography, this research ushered in a new epoch of understanding. The book is now available in an English translation, published by Imperial College Press.

Embryology of the Heart

ANTOON F.M. MOORMAN, NIGEL BROWN, and ROBERT H. ANDERSON

Much has been learnt since the second edition of the book was published. It remains a fact that, as was emphasised at the start of this chapter in the second edition, from the functional point of view the heart is simply a specialised part of the vascular system. The development of the heart as a specialised pump, nonetheless, is obviously of great significance, as is the formation of a coelomic cavity around the developing organ so as to aid its action. We have learnt a great deal over the past decade regarding the origin of the muscular parts of this pumping organ. In the previous edition, emphasis was placed on the so-called segments of the developing heart tube, since it was believed that the initial linear tube contained the precursors of the components as seen in the postnatal heart. We now know that this is not the case, and that tissue is continually added to the heart tube as it grows and loops. The initial straight part of the tube (Fig. 3-1) eventually forms little more than the left ventricle. This knowledge now permits us better to interpret the morphogenesis of many congenital cardiac malformations. Embryology, therefore, is no longer a hindrance in this regard, as one of us stated somewhat controversially over 2 decades ago.¹ It is the new evidence that has emerged concerning the appearance of the cardiac components that we will emphasise in the opening sections of our chapter. Thereafter, we will revert to providing an account of the various cardiac segments, as was done in the second

edition.² In this respect, we should emphasise, again as was done in the second edition, that we do not use *segment* in its biological sense when describing the development of the cardiac components. Thus, we do not imply that each purported segment is identical to the others, as is seen in invertebrates such as annelids. As explained in Chapter 1, however, the so-called segmental approach is now the preferred means of describing the cascade of information acquired in interrogating cardiac structure during the diagnostic process. As in the previous edition, therefore, we will continue to describe the cardiac components as segments, hoping to provide the necessary background to understand the anomalous development that leads to congenitally malformed hearts with abnormal connections between them. It is also the case that there are discrepancies between the terms used by biologists to describe developing heart and the attitudinally appropriate terms used by clinicians when describing the formed organ. Biologists and embryologists use the term anterior to describe structures that are towards the head, and posterior for those towards the feet. We circumvent these problems by describing cranial and caudal structures. So as to avoid confusion, we also need to avoid use of these terms when describing those structures located towards the spine and sternum, as is the wont of clinicians. For this purpose, we will use the adjectives dorsal and ventral. Right and left, of course, retain their time-honoured usage.

Figure 3-1 The heart tube has been visualised in the developing mouse embryo by detection of the expression of myosin heavy chain. It used to be thought that all parts of the organ were represented in the so-called linear tube. We now know that this part gives rise only to the definitive left ventricle and the ventricular septum. Note that there is already an asymmetrical arrangement of the tube, as shown by the *arrow*. The embryo is at about 8 days of development, which is comparable to about 21 days of human development.

ORIGIN OF THE HEART TUBE

Recent molecular studies³⁻⁵ have validated the time-honoured concept⁶⁻⁸ that, after formation of the linear heart tube (see Fig. 3-1), cells are continuously added at both its venous and arterial poles. The source of this new material has been called the second heart field, albeit that the difference between this purported second field and the presumptive primary field has not adequately been defined.⁹ Despite this lack of adequate definition, the rediscovered information has revolutionised our understanding of the building plan of the heart. Acceptance of this concept of temporal addition of new material to the heart has also helped our understanding of cardiac morphogenesis, but new questions arise. Are there two developmental fields as opposed to just one, or three, or perhaps more? How are the alleged fields distinguished from the surrounding tissues, and from each other? Do the fields represent territories of gene expression, or of morphogenetic signaling? Most importantly, do the alleged first and second fields represent distinct cellular lineages, the descendants of which form distinct compartments within the definitive

Figure 3-2 The cartoon shows how the embryonic disc is formed as a trilaminar structure, with the mesodermal structures sandwiched between the endodermal and ectodermal layers. In the cranial part of the embryonic disc, the ectoderm has been removed to visualize the cranial mesoderm. All mesoderm, including the so-called cardiac crescent, is derived from the primitive streak, as shown in Figure 3-3.

heart? An understanding of the mechanics of formation of the cardiac tube can provide some answers to these questions.⁹

Subsequent to gastrulation, the embryo possesses three germ layers. These are the ectoderm, which faces the amniotic cavity, the endoderm, which faces the yolk sac, and the intermediate mesodermal layer (Fig. 3-2). At this stage, we can recognise the so-called embryonic disc, marked by the junction of the developing embryo itself with the extraembryonic tissues formed by the amnion and yolk sac. It is subsequent folding of this disc, concomitant with extensive growth, that gives the embryo its characteristic shape. Eventually, the original junction between the disc and the extraembryonic tissues becomes the navel of the embryo. As part of this process of remodelling, the parts of the disc initially positioned peripherally attain a ventral location within the embryo. At the initial stage, the region where ectoderm and mesoderm face one another without interposing mesoderm, is the stomato-pharyngeal membrane, which closes the orifice of the developing mouth. This membrane is flanked centrally by pharyngeal mesoderm that, in turn, is bordered peripherally by the cardiogenic mesoderm. The cardiac area is itself contiguous with the mesoderm of the transverse septum, in which will develop the liver. This transverse septum is the most peripheral part of the mesodermal layer of the embryonic disc and, after the completion of folding, it is located cranial to the navel.

During the process of gastrulation, the cells that will form the heart migrate from the anterior part of the primitive streak. Subsequent to their migration, they give rise to two heart-forming regions in the mesodermal germ layer. These areas are positioned on either side of the midline.¹⁰⁻¹²

Figure 3-3 The cartoon shows how cells migrate from the primitive streak bilaterally to form first the heart-forming areas, and then the cardiac crescent. There are then temporal migrations of heart-forming cells from the cardiac crescent into the developing heart tube, with two of these migrations currently considered as the first and second heart-forming regions, or heart fields, although it is debatable whether these are discrete areas (see text for further discussion).

With continuing development, they join across the midline to form a crescent-shaped area of epithelium (Fig. 3-3). It is this tissue which subsequently provides the material for the heart tube, albeit in complex fashion. Initially, the crescent becomes a trough, which starts to close dorsally along the margins closest to the developing spine. Starting at the level of the part of the tube that will eventually become the left ventricle, closure proceeds by a process of zipping, the edges of the trough coming together in both cranial and caudal directions (Fig. 3-4). After the process of folding, the part of the crescent that was initially positioned centrally retains this position, becoming positioned medio-dorsally in the formed body. The peripheral part of the crescent, in contrast, becomes the ventral part of the definitive heart tube. It is the centro-medial part of the initial heart-forming area that several investigators have described as the secondary, or anterior, heart field.³⁻⁵ Its location permits it to contribute to those parts of the heart that develop at the arterial pole, specifically the right ventricle and outflow tract, and also to those which will form at the venous pole. At the venous pole, there is formation of the so-called mediastinal myocardium,¹³ this area eventually providing the site of entry for the pulmonary veins.^{14,15} The peripheral part of the initial crescent flanks the transverse septum, which is the site of formation of the liver, and the location of the termination of the systemic venous tributaries.

It follows from the description given above that the tissues directly adjacent to the cardiac crescent are made of pharyngeal mesoderm. From the outset, therefore, the tissues that will form the right ventricle and outflow tract at the arterial pole are directly adjacent to the developing pharyngeal arches. This pharyngeal mesoderm, also containing cells derived from the so-called second heart field, eventually provides the tissues not only for the myocardial components of the right ventricle and outflow tract, but also for the non-myocardial intrapericardial arterial trunks and their valves and sinuses.

Figure 3-4 The cartoon shows the steps involved in folding of the cardiac crescent to become a tube. The heart-forming area is viewed from the dorsal aspect, with the insets within the boxes showing the arrangement as seen from the left side. Note that the initial outer part of the crescent (red line) becomes translocated ventrally during the process of folding, with the inner part (blue line) taking up a dorsal location. D, dorsal; V, ventral.

It has been analyses of molecular lineage that have demonstrated in unambiguous fashion that myocardium is added to the already functioning myocardial heart tube.^{16,17} Thus, use of these techniques revealed a similar programme to that observed in the differentiation of the primary heart field, involving the transcription factors *Nkx2-5*, *Gata4* and *Mef2c*, as well as fibroblast growth factors and bone morphogenetic proteins.⁵ Differences in opinion remain regarding the structures formed from the so-called second field. One group has argued that this field forms only the outflow tract,⁴ but another group claims that, as well as the outflow tract, the field also gives rise to the non-myocardial but intrapericardial portion of the arterial pole.⁵ Such differences may be more apparent than real, since boundaries between morphological regions are not necessarily formed at subsequent stages by the same cells as were present initially. Interpretation has also been hampered by assumptions that, in avian hearts, the right ventricular precursors are derived from the initial linear heart tube, which contains the precursors of only the left ventricle in mammals.¹⁷ It is now known that, in the developing avian heart, as in the mammalian heart, if the straight tube is labelled at the pericardial reflection of the arterial pole,¹⁸ the entirety of the right ventricle is seen to be added to the linear heart tube later in development, consistent with the data derived in the mouse.³

Some authors¹⁹ have already suggested that there is complex patterning in the primary heart field, rather than the existence of multiple fields. Based on our interpretation of the processes of folding that lead to the formation of the linear heart tube (see Fig. 3-4), we endorse this notion.⁹ Acceptance of the notion, nonetheless, carries with it the implication that the cells within this solitary field initially have the capacity to form all parts of the

heart, depending on their position in the field. This, in turn, is in keeping with current views on cellular diversity, since differences in the concentration of diffusing morphogens can create a number of different fates for a given cell, promoting diversity within a field that was initially homogeneous.

Even if we accept that the material from which the heart is formed is derived from the same basic field, there is an obvious temporal order in the differentiation of the alleged first and second cardiac heart-forming regions. This order does no more than reflect the evolutionary development of the cardiovascular system. When initially developed during evolution of the animal kingdom, the heart contained no more than the components of the systemic circulation, namely an atrium with left and right appendages, a ventricle, and a myocardial outflow tract. The pulmonary circulation, represented by the right ventricle, and the dorsal atrial wall, including the atrial septum, appears appreciably later in evolutionary development. Within the evolutionary tree, it is in the lungfish that the pulmonary veins are first seen to unite, and drain directly to the left atrium. This sets the scene for a separate pulmonary circulation, and also for the appearance of the atrial septum. It cannot be coincidental, therefore, that the atrial septum in mammals, along with the dorsal atrial wall, is formed from mediastinal myocardium.¹³ This mediastinal myocardium, along with the right ventricle, is added to the heart relatively late in its development. The evolutionary considerations suggest strongly that novel patterning, with different temporal sequences, but within a single heart field, is sufficient to provide all the material needed to construct the four-chambered hearts of birds and mammals, albeit that not all precursors are present in the linear heart tube when it first appears (see Fig. 3-1).

Figure 3-5 This scanning electron micrograph shows the developing mouse heart during the process of so-called looping. The ventricular part of the tube has inlet and outlet components formed in series.

FORMATION OF THE CARDIAC LOOP

When first seen, the developing heart is more or less a straight tube (see Fig. 3-1). Very soon, it becomes S-shaped (Fig. 3-5). The changes involved in producing the bends are described as looping. It had been thought that the curvatures produced were the consequence of rapid growth of the tube within a pericardial cavity that expanded much more slowly.²⁰ Experiments showed that the tube continues to loop even when deprived of its normal arterial and venous attachments,²¹ and also loops when no longer beating, ruling out the role of haemodynamics as a morphogenetic factor.²² Looping, therefore, is an intrinsic feature of the heart itself, albeit that the exact cause has still to be determined. Be that as it may, the tube usually curves to the right. This rightward turning is independent of the overall

left–right asymmetry of the developing embryo. It is often said that rightward looping is the first sign of breaking of cardiac symmetry. This is incorrect. Asymmetry is evident in the structure of the atrioventricular canal when it is first seen (see Fig. 3-1),²³ but asymmetry can even be seen in the morphology and extent of the heart-forming fields.¹³

THE CARDIAC COMPONENTS

Only after looping of the heart tube has taken place is it possible to recognise the appearance of the building blocks of the cardiac chambers, along with the primordia of the arterial trunks, and the venous tributaries. In the second edition of this book, it was suggested that five segments could be seen in the developing tube, on the basis of constrictions between the various parts, and that these constrictions played important roles in further development. As has been explained above, we now know that this is not the case.

The development of the cardiac chambers depends on ballooning of their cavities from the lumen of the primary heart tube. Addition of new material from the heart-forming area produces the primordia of the right ventricle and outflow tract at the arterial pole, whilst addition of material at the venous pole produces initially the atrioventricular canal, followed by the atrial primordium, to which drain the systemic venous tributaries. The addition of this material is part and parcel of the appearance of the looped tube. Subsequent to looping, the cells making up the larger part of the tube are negative for both connexin40 and atrial natriuretic factor, permitting them to be labelled as primary myocardium (Fig. 3-6).

As the parts of the cavity begin to balloon out from both the atrial and ventricular components of the tube, so does the myocardium forming the walls of the ballooning components change its molecular nature, being positive for both connexin40 and atrial natriuretic peptide (Fig. 3-7). This myocardium is called chamber, or secondary, myocardium. The parts ballooning from the atrial component do so symmetrically with the newly formed pouches appearing to

Figure 3-6 The adjacent sections processed to show expression of either connexin40 (Cx40) or atrial natriuretic factor (ANF) show how it is possible to distinguish three specific myocardial phenotypes. The mediastinal myocardium is shown in the red oval, the primary myocardium of the atrioventricular canal by the braces and the chamber myocardium by the arrows. The embryo is at about 9.5 days of development, which is comparable to about 4 weeks of human development.

Molecular phenotype

Cx402/ ANF2:
Primary Myocardium

Chamber Myocardium

Cx401/ ANF2:
Mediastinal Myocardium

Figure 3-7 The scanning electron micrograph of a murine heart shows how the developing atrial appendages balloon forward to either side of the developing outflow tract.

either side of the outflow tract. The pouches will eventually become the atrial appendages. Examination of the atrial component of the heart at this early stage, however, reveals the presence of a third population of cells. These cells are positive for connexin40, but negative for atrial natriuretic peptide. They make up the part of the tube that retains its connection with the developing mediastinum through the dorsal mesocardium, and hence are described as being mediastinal myocardium.¹³ These cells will eventually form

the dorsal wall of the left atrium, or pulmonary venous component, a small part of the dorsal wall of the right atrium bordered at the right side by the left venous valve and at the left side by the primary atrial septum, which also is derived from the mediastinal component (Fig. 3-8). From the stance of lineage, the cells are derived from the mesenchyme of the mediastinum that surrounds the developing lung buds.²⁴ There is also ballooning of cavities from the ventricular part of the heart tube. Unlike the situation in the atrial component, where the appendages of both definitive atriums balloon in parallel, the pouches that will eventually form the apices of the left and right ventricles balloon in sequence from the ventricular loop (Fig. 3-9). The apical part of the developing left ventricle balloons from the inlet part of the loop, whilst the apical part of the developing right ventricle takes its origin from the outlet part of the loop. Concomitant with the ballooning of these two parts, so the muscular ventricular septum is formed between the apical components (see Fig. 3-9), albeit that the cells of the septum largely belong to the left ventricle. The cells making up the walls of the ballooned segments are composed of secondary, or chamber, myocardium (see Fig. 3-6). Ballooning of the chamber myocardium sets the scene for septation of the atrial and ventricular chambers. For this to be achieved, however, appreciable remodelling is required in the initial cavity of the primary heart tube. This is because, subsequent to looping and the initial phases of ballooning, the circumference of the atrioventricular

Figure 3-8 The cartoon shows how the atrial appendages, and the ventricular apical components, both coloured in yellow, have ballooned from the primary heart tube, shown in grey. The cartoon does not represent a particular stage of development but tries to bridge the transition of the primary heart tube into a four-chambered heart. The cardiac cushions are not represented in this cartoon, and the outflow tract has been bent to the right to visualize the inner curvature. Note the location of the mediastinal myocardium, which gives rise to the primary atrial septum, and encloses the opening of the pulmonary vein (see text for further discussion). (Modified from Moorman AFM, Christoffels VM: Cardiac chamber formation: Development, genes and evolution. *Physiol Rev* 2003;83:1223-1267.)

Figure 3-9 This scanning electron micrograph of a mouse heart shows how ballooning of the apical parts of the ventricles is associated with formation of the apical part of the muscular interventricular septum (star). Note that there is already a direct communication from the atrioventricular canal to the right ventricle (RV) (arrow), even though the canal is supported in its greater part by the developing left ventricle (LV) (see Fig. 3-10). The atrioventricular cushions (brace) occupy almost entirely the atrioventricular canal, leaving very narrow channels draining to the ventricles. The embryo is at about 10 days of development, which is comparable to 5 weeks of human development.

Figure 3-10 The cartoon shows how the separate streams through the heart exist from the outset of development. The outlet segment of the heart tube is supported for the most part by the outlet part of the ventricular loop, from which will form the right ventricle, but again a direct connection already exists through the lumen of the tube between the developing left ventricle and the arterial segment. It is the remodelling of the lumen of the primary tube, along with the concomitant rearrangements of the junctions with the developing atrial and arterial segments, that underscores the definitive arrangement, permitting effective closure of the plane between the bloodstreams. AV, atrioventricular.

canal is attached in its larger part to the inlet of the heart tube, albeit that a direct connection already exists from its right side to the developing outflow tract (Fig. 3-10).

DEVELOPMENT OF THE VENOUS COMPONENTS

Subsequent to the process of looping, the venous pole of the heart tube shows a good degree of symmetry. Venous tributaries from both sides of the embryo itself, along with bilateral channels from the yolk sac, and from the placenta, drain into the atrial component of the tube through confluent orifices (Fig. 3-11). These structures are often described as the sinus venosus, with the channels draining to the atrial component identified as the horns of this venous sinus. Such a discrete component of the heart is to be found in lower animals, such as fish. No anatomically discrete structure is seen, however, in the early stages of development of the mammalian heart.¹⁴ The venous tributaries on both sides of the embryo simply empty into the atrial component through the confluent right- and left-sided channels (see Fig. 3-11). At the initial stages, there are no landmarks indicating the junction of these venous channels with the atrial component. It is not until the systemic venous tributaries have remoulded so as to drain asymmetrically to the right side of the atrial component that structures are seen demarcating their borders, these structures then being recognised as the valves of the systemic venous sinus (Fig. 3-12). A key part of normal development, therefore, is remoulding of the systemic venous tributaries so that they open exclusively to the right side of the developing atrial component. This process involves the formation of anastomoses between

Figure 3-11 This scanning electron micrograph showing the atrial component of the developing heart reveals how the heart tube remains connected to the pharyngeal mesenchyme through the dorsal mesocardium, and how there are no boundaries at this stage between the atrial component and the systemic venous tributaries. Already, however, the confluence of the left-sided tributaries is smaller than the right-sided confluence. The embryo is at about 9 days of development, equivalent to about 4 weeks in humans.

Figure 3-12 This scanning electron micrograph, at a slightly later stage than shown in Figure 3-11, shows how the systemic venous tributaries have become connected to the right side of the atrium, and how their junctions with the atrium have become distinct as the valves of the systemic venous sinus. Note the pulmonary ridges marking the site of the dorsal mesocardium (see Fig. 3-11), and the walls of the left venous confluence in the developing left atrioventricular groove. The embryo is at about 10 days of development, equivalent to 5 weeks of human development.

right- and left-sided components of the various venous systems so that the left-sided venous return is shunted to the right side of the embryo. The major anastomosis formed in the caudal part of the embryo results in all the umbilical venous return from the placenta being diverted to the caudal part of the cardinal venous system. This anastomotic channel persists as the venous duct. The vitelline veins largely disappear, with some of these structures being incorporated into the venous system of the liver as this structure develops in the transverse septum. A second important anastomosis develops in the cranial part of the embryo, the left brachio-cephalic vein, this channel serving to divert the venous return from the left-sided to the right-sided cardinal vein. With this shift of the cranial venous return to the right-sided cardinal channel, and with the disappearance of the

Figure 3-13 This scanning electron micrograph shows the dorsal aspect of a human heart subsequent to incorporation of the left-sided venous confluence into the left atrioventricular junction. Note that, at this stage, the pulmonary veins open through a solitary orifice immediately cranial to the left-sided venous confluence, this being the left sinus horn. The embryo is at about 6 weeks of development.

left-sided vitelline and umbilical veins, there is gradual diminution in size of the atrial orifice of the left-sided venous confluence. As this structure diminishes in size, so its walls become incorporated into the left half of the developing atrioventricular junction (Fig. 3-13). It has been suggested that a left sinuatrial wall is required to separate this channel from the left side of the developing atrium.²⁵ This is not the case. The left venous confluence simply retains its own walls as it is incorporated into the developing left atrioventricular groove. Subsequent to the rightward shift of the systemic venous orifices, the valvar structures appear, which then permit anatomical distinction between the systemic venous sinus and the remainder of the developing right atrium. The cranial and caudal right-sided cardinal veins, along with the orifice of the left systemic venous confluence, now open within their confines.

Remodelling of the systemic venous sinus also sets the scene for development of the pulmonary venous system. The pulmonary veins, of course, cannot appear until the lungs themselves have formed. These develop as buds on the ends of the bifurcating tracheo-bronchial tube, this structure extending from the ventral aspect of the gut, the lungs developing in the ventral part of the mediastinal mesenchyme. A further venous channel then develops from a mid-line strand formed within the mediastinal tissues.²⁶ This channel, when canalised, drains the developing intrapulmonary venous plexuses from both lungs, and joins the heart at the site of the persisting part of the dorsal mesocardium (Fig. 3-14; see also Fig. 3-13). This part of the mesocardium persists as most of the initial structure breaks down during looping, and continues to attach the most dorsal part of the atrial component of the heart tube to the mediastinum. When the channel is viewed internally, its edges are seen

Figure 3-14 This section from a human embryo of about 5½ weeks of development, in four-chamber plane, shows the orifice of the solitary pulmonary vein sandwiched at this stage between the left-sided venous confluence (star), now incorporated into the left atrioventricular (AV) groove, and the remainder of the systemic venous sinus (SVS), now an integral part of the developing right atrium. Note the connection with the pharyngeal mesenchyme (arrow). This is the vestibular spine.

as two ridges that bulge into the lumen of the atrial cavity (see Figs. 3-11 and 3-12). These are the pulmonary ridges. After the pulmonary venous channel has canalised within the mediastinum, it opens to the atrial cavity between these ridges, appearing initially as a midline structure, with its opening directly adjacent to the developing atrioventricular junction (Figs. 3-15 and 3-16).

For over a century there has been controversy as to the relationship between this newly formed pulmonary venous confluence and the tributaries of the systemic venous sinus. From the stance of the morphology,^{15,27,28} and the lineage of the cells forming the pulmonary vein,^{13,24,29} the evidence is now overwhelming that, during normal development, the pulmonary venous structure has never had any connection with the systemic venous tributaries. It forms as a new structure within the mediastinum, and opens within

Figure 3-15 This section, also from a human embryo, and at a comparable stage to that shown in Figure 3-14, is cut in the long-axis plane. It shows the location of the solitary pulmonary venous orifice immediately cranial to the venous confluence, now incorporated into the left atrioventricular junction as the coronary sinus.

Figure 3-16 This scanning electron micrograph of a heart of a mouse embryo at 10 days of development shows the relationship of the pulmonary vein, systemic venous sinus and primary atrial septum. The atrial orifice of the pulmonary vein is directly cranial to the walls of the left venous confluence, by now incorporated into the left atrioventricular junction, and recognisable in the developing human embryo as the coronary sinus (see Fig. 3-15).

the mediastinal myocardium to the left atrium. As such, it is positioned to the left of the site of appearance of the primary atrial septum, which is also derived from mediastinal myocardium (see Fig. 3-8). The pulmonary venous structures are also recognisable from the outset as being derived from mediastinal myocardium, whereas the systemic venous tributaries initially possess a primary myocardial lineage. We have now also shown that the systemic venous tributaries can be identified in molecular terms by their expression of the transcription factor *Tbx18*. The pulmonary veins, in contrast, do not contain this protein.³⁰ When the pulmonary vein first appears, it is a mid-line structure which drains to the heart directly adjacent to the atrioventricular junction. It is only appreciably later in the development in the human heart that the venous component of the left atrium is remodelled so that, at first, separate orifices appear to drain the blood from the right and

left lungs (Fig. 3-17). And it is then later still, indeed not until the completion of atrial septation, that the pulmonary venous component achieves its definitive position at the roof of the left atrium, with separate orifices on both sides for the superior and inferior veins from each of the two lungs (Fig. 3-18).

Only at this stage, when there are four pulmonary venous orifices, is it possible to see formation of the so-called secondary atrial septum. This so-called septum, in the postnatal heart, is no more than the fold between the right-sided pulmonary veins and the systemic venous tributaries (Fig. 3-19). It is not produced during development until the pulmonary channels are incorporated into the atrial roof (see Fig. 3-18). Such a superior interatrial fold is lacking in abnormal human hearts having totally anomalous pulmonary venous connection.

Figure 3-18 This section, again from a human embryo after the completion of septation, is at a later stage than the one shown in Figure 3-17. Note the diminution in size of the left superior caval vein, and the deepening of the superior interatrial fold, which now provides a superior buttress for the flap valve of the oval foramen. The vestibular spine and mesenchymal cushions have now muscularised to form the inferior buttress of the atrial septum.

Figure 3-17 This four-chamber section is from a human heart after the completion of septation, at about 9 weeks of development, but before the pulmonary veins are completely incorporated into the atrial roof. Note the size of the coronary sinus (*star*) and that the superior interatrial infolding is as yet incomplete (*arrow*). Note also the muscularising vestibular spine and the forming tendon of Todaro.

Figure 3-19 This four-chamber section is taken through the atrial chambers of an adult heart, and shows the definitive arrangement of the deep superior interatrial fold (*arrow*), the oval foramen (*brace*) and the antero-inferior muscular buttress. RPV, right pulmonary vein; SCV, superior caval vein.

SEPTATION OF THE ATRIAL CHAMBERS

With the initial rightward shift of the tributaries of the systemic venous sinus, the stage is set for septation of the atrial component of the heart. As the systemic venous sinus reorients relative to the developing atrium, the addition of the new mediastinal myocardium forms the larger part of the body of the developing atrial component (see Fig. 3-8). The atrioventricular canal, of course, was present from the outset, and is composed of primary myocardium. The myocardium of the atrial component itself was also initially composed of primary myocardium, but as we have shown, the two appendages bud dorsocranially in symmetrical lateral fashion from this lumen, passing to either side of the developing outflow tract. With the rightward shift of the systemic venous tributaries, and the appearance of the mediastinal myocardium, so there is also a rightward shift of the dorsal corridor of primary myocardium that continues to form the floor of the systemic venous sinus. It is at this stage that we first see the appearance of the primary atrial septum, or septum primum, which grows as an interatrial shelf from the atrial roof (see Fig. 3-16). By the time that the primary atrial septum appears, endocardial cushions have also developed within the atrioventricular canal, these structure growing towards each other so as eventually to divide the canal itself into right-sided and left-sided channels (Fig. 3-20). As the cushions grow towards each other to divide the canal, so the primary septum grows towards the cushions, carrying on its leading edge a further collection of endocardial tissue, the so-called mesenchymal cap. By the time the primary septum and mesenchymal cap approach the cushions, the cranial part of the septum, at its origin from the atrial roof, has broken down, creating the secondary interatrial foramen. The primary foramen is the space between the mesenchymal cap and the fusing atrioventricular endocardial cushions (Fig. 3-21). It is then fusion of the mesenchymal cap with the endocardial cushions that obliterates the primary atrial foramen. This process occurs to the right side of the pulmonary ridges, so that the solitary opening of the newly canalised pulmonary vein is committed to

Figure 3-20 This scanning electron micrograph shows the atrioventricular junctions of the developing human heart from the ventricular aspect just prior to fusion of the atrioventricular (AV) endocardial cushions. The embryo is at about 6 weeks of development.

Figure 3-21 This image, in four-chamber plane, is from the same embryo as shown in Figure 3-14. This section shows the primary atrial septum, with its mesenchymal cap, growing towards the superior atrioventricular (AV) cushion. Note the primary (brace) and secondary (arrow) interatrial communications. SVS, systemic venous sinus.

the left side of the dividing atrial component, the orifices of the systemic venous tributaries, enclosed within the systemic venous valves, obviously being committed to the right side of the atrium by this selfsame process. The base of the newly formed atrial septum, formed by the mesenchymal cap, is then further reinforced by growth into the heart of mesenchymal tissue through the right pulmonary ridge (see Fig. 3-14). This process was initially illustrated by Wilhelm His the Elder, who called the protrusion seen in the caudal wall of the atrium the vestibular spine, or *spina vestibuli*.³¹

The mesenchymal tissue of the spine, together with the mesenchymal cap on the primary septum, then muscularises to form the buttress at the base of the atrial septum, anchoring the septum firmly against the central fibrous body, itself formed from the fused atrioventricular cushions (see Figs. 3-17 and 3-18). The so-called sinus septum is no more than the bifurcation between the orifice of the inferior caval vein and the coronary sinus within the confines of the valves of the systemic venous sinus. The right valve itself persists to varying degrees in the definitive heart, remaining as the Eustachian valve adjacent to the opening of the inferior caval vein, and the Thebesian valve in relation to the opening of the coronary sinus. These two valves join together in the musculature of the so-called sinus septum and, in the definitive heart, a fibrous structure extends through the newly muscularised buttress at the base of the atrial septum (see Fig. 3-17), extending forward to insert into the central fibrous body. This is the tendon of Todaro, an important landmark to the site of the atrioventricular conduction axis.

Subsequent to these changes, the base of the atrial septum separates the newly formed right and left atriums, but a foramen is still present at the atrial roof. This hole is an essential part of the fetal circulation, permitting the richly oxygenated placental return to reach the left side of the developing heart so as to pass to the developing brain. As explained, not until the pulmonary veins are incorporated into the atrial roof does the upper margin of this foramen become converted into the interatrial fold, often described inaccurately as the secondary atrial septum. It is the formation of the fold that provides the buttress for the flap valve

of the definitive oval foramen, the flap itself being formed by the primary atrial septum (see Fig. 3-19). This process is not completed until well after the finish of definitive cardiac septation.²⁸

After the formation of the primary atrial septum, and its reinforcement by the vestibular spine, the atrial chambers have effectively been separated one from the other. As also explained, the septum initially grows between the site of the left venous valve and the orifice of the newly formed pulmonary vein. All the tissue to the left of the venous valve is mediastinal myocardium (see Fig. 3-8), and it is this tissue which represents the body of the developing atrium. The larger part of this body is, therefore, committed to the definitive left atrium subsequent to atrial septation. If we summarise the development of the atrial components, each atrium possesses a part of the body derived from mediastinal myocardium, with the larger part committed to the morphologically left atrium. Each atrium also possesses an appendage, formed by budding from primary myocardium of the heart tube and differentiation into secondary, or chamber, myocardium, and a vestibule, derived from the initial primary myocardium of the atrioventricular canal. The venous components, in contrast, have disparate origins. The systemic venous myocardial component is formed by differentiation of Tbx18-positive mesenchyme into myocardium. The pulmonary venous myocardial component, in contrast, is derived, along with the atrial septum, from Islet1-positive mediastinal mesenchyme, itself developing from what some call the secondary heart field.

THE ATRIOVENTRICULAR CANAL

In early stages, the junction between the developing atrial component and the inlet of the ventricular loop is indeed a canal with a finite length (see Fig. 3-15). The canal itself is septated by fusion of the superior and inferior atrioventricular endocardial cushions (see Fig. 3-20). His³¹ described the fused cushions as producing the intermediate septum. It is this part of the septum that is buttressed by the ingrowth of the vestibular spine, with muscularisation of the spine and mesenchymal cap forming the prominent infero-anterior rim of the oval fossa seen in the definitive heart (see Figs. 3-17 and 3-18). The cushions themselves, as we will describe subsequently, provide the foundations for formation of the aortic leaflet of the mitral valve, and the septal leaflet of the tricuspid valve. They also contribute to closure of the interventricular foramen, forming in the process the membranous part of the septum. Only subsequent to delamination of the septal leaflet of the tricuspid valve, a relatively late event, does this part become separated into atrioventricular and interventricular portions.³²

Much has been learned in recent years concerning the endothelial to mesenchymal transformations that take place during formation of the atrioventricular cushions.³³ These events are not directly relevant to an understanding of cardiac development. It was thought, in the past, that failure of fusion of the cushions underscored the development of hearts with atrioventricular septal defect and common atrioventricular junction, for quite some time these lesions being labelled as endocardial cushion defects.³⁴ We now know that abnormal hearts can develop

with all the features of atrioventricular septal defect subsequent to fusion of the cushions, albeit that the cushions themselves are abnormal. The problem underscoring the abnormality is one that permits the retention of the common junction, probably involving abnormal formation of the vestibular spine.^{35,36} Irrespective of such niceties, there is no question but that, during normal development, the atrioventricular cushions fuse with each other to divide the atrioventricular canal into right-sided and left-sided channels (see Fig. 3-20). With ongoing development, part of the musculature of the atrioventricular canal becomes sequestered as the atrial vestibules. We know this because of studies made using an antibody prepared against the nodose ganglion of the chicken.³⁷ These studies proved that this antibody, subsequent to formation of the ventricular loop, marked serendipitously a ring of cells in the developing human heart that surrounded the primary foramen (Fig. 3-22). The marked area extended from the crest of the muscular ventricular septum and included the right side of the atrioventricular canal. When human embryos were then studied subsequent to formation of the right atrioventricular junction, and commitment of the right atrium to the right ventricle, the area of the atrioventricular canal initially seen to have been marked by the antibody was located in the vestibule of the right atrium, and was separated from the ventricular myocardium by the forming insulating tissues of the right atrioventricular junction (Fig. 3-23). The insights provided by the studies using this antibody showed, therefore, that part of the atrioventricular canal musculature became sequestered as the atrial vestibules with ongoing development. The studies also provided important insights into remodelling of the primary interventricular foramen, which we will discuss further in our next section. We now know that the parietal wall of the inlet of the left ventricle is also derived from the initial primary myocardium of the atrioventricular canal, at least in the mouse heart. This knowledge comes from the development of a mutant mouse in which the gene *Tbx2* was used to mark

Figures 3-22 An immuno-stained section of a human embryo at 5 weeks of development. The image shows the location of the ring of cells (double-headed arrow) demarcated by the antibody to the nodose ganglion of the chick prior to expansion of the atrioventricular canal. This ring demarcates the myocardium surrounding the so-called primary foramen, a part of the primary heart tube that defines the outlet of the forming left ventricle and the inlet of the forming right ventricle.

Figure 3-23 This image, also immuno-stained using the antibody to the nodose ganglion of the chick, shows how the interventricular ring (arrows), by 6 weeks of development has come to surround the newly formed right atrioventricular junction, along with the developing outflow tract of the aorta from the left ventricle.

the lineage of the initial myocardium in the atrioventricular canal (Fig. 3-24). The studies, as yet unpublished, showed that, whilst the parietal wall of the left ventricular inlet is marked by the gene-encoded product the greater part of the septum is free from marked cells. The septum, therefore, along with the apical component develops from the chamber myocardium of the left embryonic ventricle.

FURTHER DEVELOPMENT OF THE VENTRICULAR LOOP

The confusion that existed concerning the way in which the ventricular loop became converted into the definitive ventricles,³⁸ and which received considerable attention in the previous edition of this book,² has been resolved in part by the use of descriptive terms for the inlet and outlet parts of the loop, and in part by recognition that the apical parts of the ventricles balloon out in series from the lumen of the primary tube, the apical part of the left ventricle ballooning from the inlet, and the right ventricular apical part from the outlet (see Fig. 3-9). It had long been recognised that functional separation of the left-sided and right-sided bloodstreams had taken place long before the completion of ventricular septation, so that two parallel bloodstreams, instead of a single one, traverse the serial segments (see Fig. 3-10). Development of the ventricles simply proceeds by partitioning these bloodstreams so that the one originating from the right side of the atrioventricular canal becomes channeled to the pulmonary trunk, whilst the one commencing at the left side of the atrioventricular canal is committed to the aorta. In addition to requiring marked remodelling of the inner heart curvature, this process also requires appropriate septation of the outlet component of the primary heart tube.

Expansion of the right side of the atrioventricular junction is sufficient to place the cavity of the right atrium in more direct communication with the apical part ballooned

Figure 3-24 This image shows a cross section of a murine heart from an embryo at 17.5 days of development. The mouse has been created so as to show the lineage of the cells making up the atrioventricular canal and the outflow tract at 9.5 days of development, by crossing a *Tbx2 cre* mouse with an *R26R* mouse. Use of this lineage study means that all the cells derived from the atrioventricular canal, which is marked by *Tbx2* at 9.5 days of development, are subsequently coloured blue. As can be seen, the inlet part of the left ventricle is coloured blue, showing that the cells forming this part of the ventricle were derived from the atrioventricular canal. The septum, and the apical component, are largely unmarked. (Courtesy of Dr Vincent Christoffels, University of Amsterdam, Amsterdam, The Netherlands.)

from the outlet part of the ventricular loop. The mechanics of this expansion are well illustrated by the fate of the ring of cells marked by the antibody to the nodose ganglion of the chick, and illustrated in Figs. 3-22 and 3-23.³⁷ The fate of this ring of marked cells also shows that, during ongoing development, the outlet part of the heart tube is reorientated so that its dorsal half becomes the outlet from the left ventricle. Concomitant with this reorientation, the proximal parts of the cushions that have developed and fused to divide the outlet segment of the primary tube into pulmonary and aortic channels are brought into alignment with the crest of the muscular ventricular septum (Fig. 3-25), the latter structure, as we have already shown, being formed by the apical ballooning of the chamber myocardium of the right and left ventricles (see Fig. 3-9). This remodelling of the cavity of the initial heart tube, providing an effective inlet to the apical part of the right ventricle, and an outlet for the apical part of the left ventricle, then permits the middle part of the initial foramen to be closed by apposition of tissue derived from both the atrioventricular and outlet endocardial cushions^{39,40} (Fig. 3-26).

Before moving on to consider the formation of the atrioventricular valves, obviously crucial features of the definitive ventricles, it is convenient first to discuss the changes that take place with the outlet segment of the heart tube, and the arteries it feeds within the developing pharyngeal mesenchyme.

Figure 3-25 This section through a human embryo at about 7 weeks of development, cut in frontal plane, replicating the oblique subcostal echocardiographic cut, shows how fusion of the muscularising proximal cushions of the outflow tract with the ventricular septum walls the aorta into the left ventricle. The *star* shows the coronary sinus. Note the pulmonary venous orifice adjacent to the sinus at this stage of development.

THE OUTLET SEGMENT

It is, perhaps, the outlet segment of the heart about which we have learnt most since the appearance of the second edition of our book.² In the first place, as we have now emphasised several times, we now know that this part of the developing heart is derived from a secondary source, different at least in temporal terms from that producing the initial linear heart tube. In the second place, although the larger parts of the intrapericardial outflow tracts in the definitive heart have arterial walls, the entirety of the outlet segment, when initially formed, has walls made of myocardium. In the third place, we now know that the so-called aortic sac is little more than a manifold giving rise to the arteries that extend through the arches of the pharyngeal mesenchyme. In previous accounts, notions of division of this sac, and the outlet segment itself, by growth of an aortopulmonary septum have been grossly exaggerated. We also now know that migration of cells from the neural crest is crucial for normal development of this part of the heart, and for its separation into the pulmonary and aortic channels. In this section, therefore, we will seek to correlate

Figure 3-27 This scanning electron micrograph of a human embryo at around 6 weeks of development shows the junction of the outflow tract with the so-called aortic sac. The sac is no more than a manifold within the pharyngeal mesenchyme that gives rise to the arteries running through the pharyngeal arches, at this stage the third, fourth, and sixth arches. The *star* shows the dorsal wall of the sac, which represents the aorto-pulmonary septum.

our own findings and observations with currently existing concepts of development.

The distal extent of the developing outlet segment of the heart tube, subsequent to the completion of ventricular looping, is marked by the margins of the pericardial cavity. At this stage of development, the outlet is a tube with a solitary lumen, taking its origin from the outlet of the ventricular loop. At its distal extent, marked by the pericardial reflections, the lumen becomes confluent with the area known as the aortic sac (Fig. 3-27). At this early stage, the walls of the tube are exclusively myocardial. Endocardium is then formed in the luminal lining, again by a process of mesenchymal to endothelial transformation as occurs with the atrioventricular cushions, but the endocardial jelly

Figure 3-26 These scanning electron micrographs show the back (A) and the front (B) of a transected mouse heart at 11½ days of development, equivalent to the sixth week of development in the human. As can be seen in panel B, the embryonic interventricular foramen (*red dotted circle* in B) will be closed by adherence of the atrioventricular (AV) and outflow cushions. In this panel, the front part of the heart is viewed from behind. LV, left ventricle; RV, right ventricle.

Figure 3-28 This scanning electron micrograph of a human embryo at around 6 weeks of development shows the external aspect of a human embryo when the outflow tract is a muscular tube. Note how it is divided into proximal and distal parts by the dog-leg bend.

initially lines the entirety of the tube in circumferential fashion. When viewed externally at this stage, the tube has an obvious bend, permitting the distinction of proximal and distal parts (Fig. 3-28). At the margins of the pericardial cavity, the lumen is continuous with the space in the ventral pharyngeal mesenchyme from which originate the arteries that initially run symmetrically through the developing pharyngeal arches. These arteries encircle the gut and the developing tracheobronchial groove, uniting dorsally to form the descending aorta. Although it is frequent for cartoons representing this stage to show five pairs of arteries,

Figure 3-29 At this early stage of development of the mouse heart, at 10 days, the aortic sac gives rise to right and left horns (R, L), each of which supplies the arteries to the first three pharyngeal arches (numbered 1 to 3) in symmetrical fashion. (Courtesy of Dr. Sandra Webb, St George's Medical University, London, United Kingdom.)

Figure 3-30 This cranial view of the developing mouse heart at 11 days of development shows the stage at which the third, fourth and sixth arteries, running through the pharyngeal arches, take their origin from the aortic sac. Note that, already, the right sixth arch artery is smaller than the left one. The green tissues are the arterialisated component of the outflow tract, within the pericardial cavity. (Courtesy of Dr. Sandra Webb, St George's Medical University, London, United Kingdom.)

in reality there are never more than two or three pairs of arches, along with their arteries, to be seen at any one time. At the earliest stage, at least in the mouse, the mediastinal space has right and left horns, with each horn giving rise to the arteries of the first to third arches (Fig. 3-29). These arteries rapidly become assimilated into the arterial system of the head and face. By the time it becomes possible to recognise the arteries of the fourth and sixth arches, the arteries within the fourth arch are feeding the arteries of the third arches, and it is no longer possible to recognise the arteries of the initial two arches as encircling structures (Fig. 3-30). The cavity of the so-called aortic sac by this stage is little more than the continuation of the lumen of the outlet segment beyond the pericardial boundaries. It is still possible, nonetheless, to recognise obvious proximal and distal parts of the outlet segment, with a marked dog-leg bend between them. Within the lumen, throughout the tract, the endocardial tissue has now thickened to form opposing cushions, or ridges. When traced proximally to distally, the ridges spiral. The ridge that is parietal at the proximal end of the outlet turns beneath the other ridge at the bend, and achieves a caudal location within the distal outflow tract. The ridge that is septal proximally spirals to become positioned cranially at the distal extent of the outlet. This means that, as the ridges approximate one another, fusing along their facing surfaces, the proximal outflow tract will eventually be separated into ventral and dorsal channels, whilst fusion of the ridges distally will produce right-sided and left-sided channels. Fusion of the ridges, or cushions, however, does not occur at the same time, but rather commences distally, with the act of closure moving in proximal direction. Prior to the commencement of fusion, important changes have also taken place in the aortic sac. There is marked diminution in size of the right-sided arteries running from the sac to join the descending aorta (Fig. 3-31).

As the dorsal parts of the arteries running with the right pharyngeal arches begin to involute, so it becomes possible

Figure 3-31 The stage in the mouse heart, at 12 days of development, after remodelling of the arteries running through the pharyngeal pouches. The heart is viewed from above. Note that the systemic arteries, namely the fourth arch, arise from the cranial and rightward part of the outflow tract, again shown in green, whilst the pulmonary channels, the sixth arch, arise from the leftward and caudal part. Note also the appearance of the pulmonary arteries themselves, but that the right sixth arch has involuted (*star*). Only the left fourth arch now communicates with the descending aorta, which is left sided. Compare with Figure 3-31. (Courtesy of Dr. Sandra Webb, St George's Medical University, London, United Kingdom.)

to recognise the developing pulmonary arteries, which course caudally within the ventral mesenchyme of the mediastinum to feed the rapidly growing lung buds. The effect of these changes is that the aortic sac now gives rise to only two sets of arteries, located cranially and caudally, with the orifices of the left-sided arteries being appreciably larger than those seen to the right, particularly for the arteries running within the sixth arch. Throughout this process of remoulding, it has been the dorsal wall of the pharyngeal mesenchyme, separating the origins of the pairs of arteries running through the fourth and sixth arches, which represents the so-called aortopulmonary septum. It is this tissue that separates the flow from the cranial part of the outflow tract and aortic sac to the fourth arch and the developing brachiocephalic arteries from that flowing to the caudal part, which now feeds the two pulmonary arteries and the artery of the left sixth arch, representing the arterial duct, the right sixth arch having involuted (see Fig. 3-31). Concomitant with the remodelling of the arteries within the pharyngeal arches, cells have begun to grow from the pharyngeal mesenchyme into the distal ends of the outlet segment, growing parietally between the ends of the distal ridges or cushions to replace the initially myocardial walls. The tongues of tissue thus formed, which rapidly arterialise, produce at the same time a fishmouth appearance for the remaining myocardial margins of the outflow tract, as initially emphasised by Bartelings and Gittenberger-de Groot⁴¹ (Fig. 3-32). The tongues run between the distal extents of the cranial and caudal ridge, which reach almost to the margins of the pericardial cavity.

So as finally to separate the developing channels for the pulmonary and systemic circulations, it is necessary for the right-sided channel within the distal outflow tract to be joined to the cranial part of the persisting aortic sac, and for the left-sided channel to be directed to the floor of the aortic sac, the two pulmonary arteries, and the left-sided artery running within the sixth arch. The mechanics of this process have still to be fully elucidated, but most current

Figure 3-32 The drawing, made from the reconstruction of a human embryo reported by Bartelings and Gittenberger-de Groot,⁴¹ shows the initial regression of the muscular walls of the outflow tract at the distal margin of the pericardial sac concomitant with invasion of the walls by non-myocardial cells from the pharyngeal mesenchyme.

accounts correlate the process with growth of an aortopulmonary septum. As Los⁴² emphasised, such a septum can readily be identified in reconstructions of the lumens of the arteries arising from the aortic sac, but is difficult to identify in reconstructions of the pharyngeal mesenchyme. As we have shown, supporting the findings of Los,⁴² the aortopulmonary septum in reality is no more than the mesenchymal tissue separating the lumens of the arteries running through the fourth and sixth arches. And as can be seen in scanning electron micrographs,⁴³ this tissue is simply the most prominent of a series of interarterial structures (see Fig. 3-27).

The precise mechanics of the way in which the dorsal wall of the aortic sac, representing the aortopulmonary septum, fuses with the distal margins of the outlet ridges remains to be clarified, as does any role the ridges themselves may play in formation of the walls of the intrapericardial arterial trunks. As we have seen, nonetheless, it is the parietal portions of myocardium at the distal margins of the outflow segment that are initially replaced by ingrowths from the pharyngeal mesenchyme. Additional migrations then occur through these right and left sides of the outflow segment to populate the cushions themselves. These migrating cells are derived from the neural crest.⁴⁴ Indeed, it is the cells from the neural crest that fill the larger parts of the fusing cushions, so they could well be described as neural crest cushions, rather than endocardial cushions. The central part of the pharyngeal mesenchyme, furthermore, which forms the initial aortopulmonary septum, save for a thin luminal cap, is not populated by cells derived from the neural crest (Fig. 3-33).

It is the fusion of the distal ends of the ridges with each other, and also with the dorsal wall of the aortic sac, that serves to connect the right-sided channel within the distal outflow tract to the cranial systemic arteries, and the left-sided channel to the caudally positioned pulmonary arteries and the artery of the left sixth arch. In essence, this process obliterates a previously existing aortopulmonary foramen (Fig. 3-34). As

Figure 3-33 This frontal section shows the origin of the arteries feeding the fourth and sixth arches from the aortic sac in a mouse at about 11 days of development, and programmed to show cells derived from the neural crest as blue. The cells populate the cushions within the outflow tract, but the dorsal wall of the sac, the so-called aortopulmonary septum, does not contain cells derived from the crest. (Courtesy of Dr. Sandra Webb, St George's Medical University, London, United Kingdom.)

Figure 3-34 This sagittal section through a human embryo at 6 weeks of development shows how fusion of the distal cushions with each other, and with the dorsal pharyngeal mesenchyme (star), will close the aortopulmonary foramen, and separate the systemic (fourth arch) from the pulmonary pathways.

part of this process, there is also rapid proximal regression of the jaws of the fishmouth of outflow myocardium, so that the distal segment of the outflow tract comes to attain non-myocardial walls. There is delay in formation of the adjacent walls of the newly formed intrapericardial pulmonary trunk and aorta when compared with the parietal walls, the latter being formed, as we have described, by the initial ingrowths of non-myocardial tissue from the pharyngeal mesenchyme (Fig. 3-35). Whether the arterialising adjacent walls are derived from the distal parts of the cushions themselves, or

Figure 3-35 In this human embryo at about 6½ weeks of development, the aortopulmonary foramen has been closed, and the walls of the intrapericardial arterial trunks are arterialising. Note, however, that the parietal walls of both trunks are better formed than the adjacent walls, which are separated by a mass of tissue continuous with the pharyngeal mesenchyme (star). This tissue will eventually disappear. Note also that the cushions are still present in the proximal outflow tract, with the pulmonary valve beginning to form in the intermediate section.

are delaminated from the cranial and caudal margins of the pharyngeal mesenchyme at the margins of the pericardial cavity, has still to be determined. It is possible to recognise, nonetheless, a spur of pharyngeal mesenchyme, comparable in many ways to the vestibular spine, from which are formed at least part of the arterialising adjacent walls of the intrapericardial arterial trunks (see Fig. 3-35). This spur is the remnant of the aortopulmonary septum, which will disappear as the aorta and pulmonary trunk develop their own walls in their intrapericardial course.

At the stage at which the distal part of the outflow tract has separated into the intrapericardial parts of the aorta and pulmonary trunk, the most proximal parts of the outflow ridges remain unfused, albeit that the ridges have fused at the now separated origins of the arterial trunks. By now, additional cushions have appeared in the parietal parts of the aortic and pulmonary channels, the pulmonary cushion being placed much more cranially compared with the aortic cushion. These are the intercalated cushions. It is cavitation within the distal ends of these cushions, and also within the opposite ends of the now fused original outflow cushions, that produces the primordia of the aortic and pulmonary valves (Fig. 3-36). This process takes place within the persisting cuff of outflow myocardium, which still encloses the outflow tract as far distally as the origins of the intrapericardial arterial trunks. The site of origin of the aorta and pulmonary trunk, in the region of the bend of the outflow tract, will become the sinutubular junctions, again with the pulmonary junction located more cranially and leftward when compared with the developing aortic sinutubular junction. As the cushions cavitate, so the outside part of the cavity, next to the myocardial cuff, arterialises to become the walls of the arterial valvar sinuses, whilst the inside part of each cavity, adjacent to the arterial lumen, remodels to become the valvar leaflets.

Figure 3-36 This section from a human embryo at around 7 weeks of development has cut through the short axis of the developing arterial valves. Note that both valves are still surrounded by a myocardial cuff. The sinuses and leaflets are forming by a process of cavitation of the cushions. Note also the site of the initial zone of fusion between the cushions. The arterial roots will separate at right angles to this plane.

The opposing edges of the cushions themselves do not fuse, thus producing the trifoliate arrangement of the aortic and pulmonary valves (see Fig. 3-36). The middle part of the cushions breaks down along a line which is normal to the line of fusion so that, eventually, the newly formed aortic root is separate from the pulmonary root. This middle part of the fused cushions was initially occupied by the cells derived from the neural crest, which die during this process by apoptosis.⁴⁵

At the initial stage of formation of the arterial valves and their supporting sinuses from the middle part of the outflow tract, the proximal parts of the cushions are themselves still unfused. As these cushions fuse with each other, so they also fuse with the crest of the ventricular septum, this having been formed concomitant with the ballooning of the apical parts of the right and left ventricles. At the same time, there is muscularisation of the most proximal part of the fused cushions, whilst the middle part, occupied by the cells migrating from the neural crest, again disappears by the process of apoptosis. In this way, the caudal part of the proximal outflow tract becomes committed to the left ventricle, taking with it the newly formed aortic valve, while the cranial part now forms the exclusive outlet from the right ventricle, feeding the newly formed pulmonary valve. The muscularised part of the fused proximal cushions becomes the subpulmonary infundibulum, while the apoptosis of the cells migrating from the neural crest creates the tissue plane which separates the subpulmonary infundibulum from the aortic root (Fig. 3-37). At the stage at which the proximal parts of the fused outflow cushions themselves fuse also with the crest of the muscular ventricular septum, so the remaining interventricular foramen is closed by apposition of the outflow cushions with the atrioventricular cushions (see Fig. 3-25).³⁹ At this stage, the musculature of the inner heart curvature continues to separate the developing leaflets of the aortic valve, by now committed to the left ventricle, from the forming aortic leaflet of the mitral valve. It is only at a much later stage

Figure 3-37 The cartoon shows how the distal part of the outflow tract has formed the intrapericardial parts of the arterial trunks (green), and the middle part has given rise to the valvar leaflets and their supporting sinuses (yellow), while the proximal parts of the cushions muscularise to form the subpulmonary infundibulum (pink). The core of the cushions, filled with cells from the neural crest (purple), disappears so as to produce the tissue plane between the infundibulum and the aortic root. The proximal cushions then fuse with the ventricular septum so as to wall the aorta into the left ventricle (see Fig. 3-25). AV, atrioventricular.

that this muscle disappears, producing the aortic-to-mitral valvar continuity that is a feature of the postnatal heart. Similarly, it is at much later stages, once more by a process of apoptosis, that the muscular cuff surrounding the developing arterial roots disappears so that the arterial valvar sinuses form the external walls of the pulmonary and aortic roots.⁴⁶

FORMATION OF VALVES

Valves are formed at several locations within the developing heart, in all instances preventing regurgitation to a proximal segment. This is the only common feature, since there are marked differences in both morphogenesis and final structure at the various levels.

The Sinuatrial Valves

The valve-like structures seen at the sinuatrial junction are most conspicuous during the stages of development. The left-sided valve of the systemic venous sinus reinforces the right side of the developing atrial septal structures, albeit that, when first seen, an intersepto-valvar space can be recognised, the wall of this space being formed from mediastinal myocardium. This is the body of the right atrium, but its site cannot be recognised in the mature heart. The right valve of the systemic venous sinus does remain recognisable,

albeit seen to various extents postnatally in different individuals. Its ventral portion persists to guard the orifice of the coronary sinus, and is known as the Thebesian valve. The dorsal part persists as the Eustachian valve, which guards the orifice of the inferior caval vein. This valve varies considerably in postnatal life. In some individuals, it may reach sufficiently far to provide a valve also for the mouth of the superior caval vein, but this is rare unless the heart itself is malformed. More usually, the Eustachian valve is not so large, and mostly disappears, leaving only a remnant attached to the muscular terminal crest. This internal ridge corresponds with the external terminal groove, and marks the boundary between the smooth-walled systemic venous sinus, initially composed of primary myocardium, and the pectinated wall of the atrial appendage formed from secondary, or chamber, myocardium. In early stages, this right valve is a muscular structure, but it becomes a fibrous flap in the mature heart.

The Atrioventricular Valves

As we have already described, the atrioventricular canal is initially lined by a continuous mass of endocardial jelly, from which develop gradually, by the process of mesenchymal to endothelial transformation, the superior and inferior atrioventricular endocardial cushions. In the early stages, these cushions themselves have a valve-like function. They also provide the scaffold for formation of parts of the definitive valvar leaflets, with their left ventricular components fusing to form the aortic leaflet of the mitral valve, and the right ventricular parts the septal leaflet of the tricuspid valve.^{47,48} Additional cushions also develop within the lateral parts of the atrioventricular canal which provide the primordia of the other valvar leaflets. There is also initially delamination of the luminal part of the ventricular myocardium at the sites of the cushions, but analysis of lineage shows that the definitive leaflets do not have a myocardial heritage, so the delaminating myocardium must subsequently disappear. The points of attachment of the myocardium within the ventricles compact as the trabeculated part of the ventricular wall also disappears, these compacted areas persisting as the papillary muscles. Not all the leaflets mature at the same time. Formation of the septal leaflet of the tricuspid valve, in particular, is an extremely late event. As we have already described, it is the final steps of this undermining that lead to differentiation of the atrioventricular and interventricular parts of the membranous septum, a process which often remains incomplete at the time of birth.³²

The Arterial Valves

We have already described the processes involved in formation of the arterial valves, and we will not reiterate this information, save to say that, as yet, we do not know how the cushions differentiate separately to form, on the one hand, the valvar leaflets, and, on the other hand, the supporting valvar sinuses.

THE CONDUCTION SYSTEM

It is, perhaps, knowledge regarding the development of the so-called conduction tissues of the heart that has been aided most by the recent development of genetic and molecular

biological techniques. As we write this chapter, it is exactly 100 years since Keith and Flack⁴⁹ described the anatomical location of the cardiac pacemaker, and just over 100 years since Sunao Tawara, a Japanese pathologist working with Aschoff in Marburg, clarified the structure of the morphological axis responsible for atrioventricular conduction, his wonderful monograph now available in an English translation.⁵⁰ Shortly after these giants described the cardiac nodes in such splendid fashion, the first suggestion was made that histologically recognisable structures joined together the pacemaker and the node responsible for delaying the cardiac impulse.⁵¹ This, in turn, triggered an important debate at the meeting of the German Pathological Society held in Erlangen in 1910, from which emerged the two publications that established the anatomical criteria for recognition of those structures that we now describe as the cardiac conduction tissues.^{52,53} On the basis of these suggestions, which retain their currency even in the era of molecular biology as the gold standard for histological recognition of the so-called conduction tissues, we can state that specialised conduction tracts need to be histologically distinct, traced from section to section in serially prepared material, and insulated by fibrous tissue from the adjacent working myocardium. The cardiac nodes are recognised on the basis of their histological characteristics, and again the ability to follow them from section to section, since it would defeat their purpose if they, too, were insulated from the adjacent myocardial tissues.

When we examine the developing heart, areas of myocardium satisfying these criteria are not recognised until the heart is well formed. Long before these stages, however, it is possible to record an electrocardiogram from the developing embryo. This is because all myocardial cells within the heart have the ability to conduct the cardiac impulse. The electrocardiogram is seen as soon as the heart tube develops areas permitting fast as opposed to slow conduction. This is seen concomitant with the appearance of the chamber, or secondary, myocardium that balloons from the linear heart tube.⁵⁴ This chamber myocardium conducts rapidly, its cells being linked by multiple connexins that are absent from the slowly conducting primary myocardium of the linear heart tube. At this early stage, of course, the primary myocardium forms the atrioventricular canal, the outflow tract and also a corridor of myocardium extending from the atrioventricular canal to incorporate the orifices of the systemic venous tributaries. In the developing murine heart, this myocardium can be recognised by its content of the transcription factor *Tbx3* gene. This gene also marks the entirety of the atrioventricular canal at an early stage, and shows the location of the ring of cells demarcated by the Gln1 antibody in the human heart, which we know will become the atrioventricular conduction axis initially demonstrated by Tawara.⁵⁰ With ongoing development, the tissues remaining positive for the transcription factor become smaller, concomitant with the development of the mediastinal myocardium, and the commitment of the systemic venous tributaries to the right atrium. Eventually, only the atrioventricular node and the sinus node remain *Tbx3* positive, although the location of the tissues initially positive for *Tbx3* within the atrial vestibules, around the mouth of the coronary sinus and along the terminal crest offers some explanation for the origins of arrhythmic activity in patients with atrial arrhythmias.⁵⁵ Initially, the myocardium surrounding both the left and right

cardinal veins displays a nodal phenotype.³⁰ This so-called sinus myocardium is derived from Tbx18-positive mesenchyme, and is gradually recruited to the myocardial lineage at the systemic venous tributaries. It is fundamentally different from the so-called pulmonary myocardium that, from the outset has a working myocardial phenotype, and is derived from Islet1-positive mesenchyme.²⁹ The tissue related to the orifice of the superior caval vein, initially the cranial cardinal vein, is known to be the site of cardiac pacemaking. We now know that it is the presence of Tbx3 that maintains the tissues added to the venous pole as the leading pacemaker,⁵⁶ and this tissue eventually forms the sinus node at the cranial cavoatrial junction, whereas the rest of the sinus myocardium differentiates into atrial working myocardium. The presence of the tracts of tissue visualised by content of Tbx3 extending between the site of pacemaking and the atrioventricular canal indicates that, early in development, all of this area was made up of primary myocardium. With ongoing growth and maturation, however, the internodal area, from the stance of histology, becomes converted into working atrial myocardium. Using the criteria established by the German pathologists, therefore, there is no evidence to support the notion that insulated tracts of histologically specialised myocardial cells join together the sinus and atrioventricular nodes. Nor does the application of these criteria lend any credence to suggestions that the cells within the pulmonary venous sleeves are histologically specialised.⁵⁷ Indeed, in this latter instance we also know that the pulmonary venous myocardium has a totally different lineage from that of the tissues forming the anatomical conduction system.^{29,30} We do know, nonetheless, that the tissues of the right atrial vestibule persist as recognisable node-like structures. These are the entities recognised by Kent at the turn of the 19th century, but erroneously interpreted by him as providing multiple muscular connections across the atrioventricular junctions of the normal heart.⁵⁸ The structures can, in very rare circumstances, function as substrates for ventricular pre-excitation in otherwise normally structured hearts,⁵⁹ and can form anomalous atrioventricular nodes in the setting of congenital malformations such as congenitally corrected transposition and double inlet left ventricle (see Chapters 31 and 39). In the course of normal development, it is only the atrioventricular conduction axis described by Tawara⁵⁰ that provides muscular continuity between the atrial and ventricular muscle masses. There have also been discussions as to whether the myocardial cells making up this axis, including the so-called Purkinje cells, are derived by recruitment of working myocardial cells, or are remnants of primary myocardium. Lineage studies now show unequivocally that the so-called conduction tissues are derived from the initial primary myocardium of the heart tube.⁶⁰

MYOCARDIAL VASCULARISATION

When the ventricular loop is first formed, there is no need for any particular system for vascularisation of the developing walls, since myocardium is broken up into a mass of individual trabeculations lined by endocardium, with little formation of a compact layer. The intertrabecular spaces, which reach almost to the epicardium, play a role subsequently in the formation of the myocardial vascular bed, albeit that it still has to be established how they are

incorporated within the forming compact component of the ventricular walls. The first indication of the epicardial trunks that feed the mural vessels is the appearance of a subepicardial endothelial plexus.⁶¹ This network subsequently establishes continuity with endothelial sprouts in the walls of the developing aortic valvar sinuses. Original theories suggested that multiple coronary arterial orifices arose from both the developing aortic and pulmonary roots.⁶² The concept was disproved when it was shown that the endothelial sprouts, which together form a peritruncal ring, invade the aortic wall from the outside.⁶³ Only two of these multiple sprouts eventually develop a lumen, thus producing the orifices of the definitive right and left coronary arteries.

MYOCARDIAL MATURATION

The maturation of the myocardium forming the ventricular walls is intimately connected to the development of the mural coronary arterial supply. Understanding of the steps involved in establishment of the compact layer of the wall has become increasingly important since the recognition of so-called ventricular non-compaction.⁶⁴ As yet, however, our knowledge of the precise steps involved in removal of the initially extensive trabecular myocardial network, and the thickening of the compact layer, remain rudimentary. It is certainly the case that in the sixth and seventh weeks of development, immediately prior to closure of the embryonic interventricular foramen, there is an extensive trabecular meshwork filling the larger part of the ventricular lumens, and the compact layer of the myocardium is very thin in relation to the thickness of the trabeculated layer (Figs. 3-38 and 3-39). At these initial stages, there is also muscular continuity across the developing atrioventricular junctions. The inner heart curvature remains as a muscular fold between the developing leaflets of the aortic and mitral valves (see Fig. 3-39). Immediately subsequent to closure of the embryonic interventricular communication, in the eighth week of development, there is a marked reduction in the extent of the trabeculations, and a thickening of the

Figure 3-38 This long-axis section of the left ventricle is from a human embryo at stage 14, in the sixth week of development. Note the extensive trabecular meshwork (yellow arrow) filling the ventricular cavity. The compact layer (red arrow) is relatively thin. Note also the muscular continuity across the atrioventricular junctions through the atrioventricular canal musculature.

Figure 3-39 This section to be compared with Figure 3-38, and also taken through the long axis of the left ventricle, is from a human embryo in the seventh week of development. There is still an extensive trabecular meshwork (yellow arrow) relative to the thickness of the compact layer (red arrow). Note the developing leaflets of the aortic and mitral valves, which are still separated by the muscular inner heart curvature. Note also the diminishing muscular continuity across the atrioventricular junction.

Figure 3-40 This section, again taken through the long axis of the left ventricle, is from a human embryo in the eighth week of development, subsequent to closure of the embryonic interventricular foramen. In comparison with the situation in the seventh week (see Fig. 3-39), there has been marked thickening of the compact layer (red arrow), and the trabeculations within the lumen are regressing. Note that the atrial myocardium is now separated from the ventricular musculature across the atrioventricular junction, but that there is still muscle between the developing leaflets of the aortic and mitral valves.

compact layer (Fig. 3-40). It seems unlikely that the trabeculations themselves coalesce to produce the compact layer, but this has still to be established with certainty. It is very likely, however, that persistence of the embryonic trabecular layer is the substrate of the morphological picture now described as ventricular non-compaction.^{64,65}

ACKNOWLEDGEMENTS

We are indebted to our colleagues at the University of Amsterdam and St George's Medical University, London, United Kingdom, for granting us permission to discuss findings, and produce illustrations, from work as yet unpublished in the peer-reviewed literature, in particular Drs Vincent Christoffels and Sandra Webb.

This series of reviews discusses recent findings in cardiac development, and offers an overview for those working in clinical disciplines. The third part of the series points out the current deficiencies in concepts explaining septation of the outflow tract on the basis of growth of an aortopulmonary septum.

Myocardium and Development

PAGE A.W. ANDERSON*

The developing heart appears to be simply a smaller version of the adult heart, based on global function. The ventricles of the adult and the developing heart fill with blood, develop pressure, eject blood, and relax (Fig. 4-1). Across development, nonetheless, ventricular myocardium differs quantitatively and qualitatively in function and structure. For example, adult myocardium develops greater active tension than does fetal myocardium, and is more compliant¹ (Fig. 4-2). When the extracellular matrix that enfolds the cells is removed, a marked developmental increase in contractility is observed in the isolated cell. The velocity and amount of sarcomeric shortening of the adult myocyte are greater than those of the immature myocyte² (Fig. 4-3). In this chapter, I review the structures and processes that are basic to cardiac function, and show how they are affected by development.

THE HEART

The volume and mass of the heart increase with development.^{3,4} The postnatal increase in left ventricular mass in the structurally normal heart is a result of an increase in the number, or hyperplasia, and in size, or physiological hypertrophy, of the ventricular myocytes, and in the growth of the non-myocytic components of the myocardium.⁵ Workload

Figure 4-1 Effects of spontaneous rhythm on left ventricular minor axis dimension (D), aortic pressure (AP), ascending aortic flow (LVO), and electrocardiogram (ECG) in an in utero fetal lamb 7 days following surgical implantation of the physiological monitoring devices. Ventricular ejection of the fetal heart is qualitatively similar to that of the adult, the only differences being the faster rate, smaller ventricular volumes and stroke volumes, and lower arterial pressure. (From Anderson PAW, Glick KL, Killam AP, Mainwaring RD: The effect of heart rate on in utero left ventricular output in the fetal sheep. *J Physiol [Lond]* 1986;372:557–573, Figure 1.)

*Sadly, Page A.W. Anderson passed on between the completion of this chapter and its production. The editors dedicate this part of the book to his eternal memory.

and mural stress directly affect mural thickness, as evidenced by the differences in thickness of the right and left ventricular free walls of the adult heart. With birth, the relative workloads of the ventricles change, with that of the left ventricle being increased. This postnatal change in workload is associated with an increase in left ventricular mass, relative to body weight, while that of the right ventricle remains the same or decreases.⁴ The ability of the developing heart to increase ventricular mass in response to an increase in mural stress is exemplified by changes in the left ventricle of the newborn with concordant atrioventricular and discordant ventriculo-arterial connections. The normal postnatal increase in left ventricular mural mass does not occur in the presence of the normal neonatal fall in pulmonary arterial pressure. If, however, the pulmonary arterial pressure is elevated in the infant through surgical

Figure 4-2 Isometric passive (resting) length-tension curves (two lower curves) and active length-tension curves (two upper curves) from fetal and adult myocardium. The adult data are in blue, and the fetal data are in red. The adult myocardium develops greater normalised active tension than does the immature myocardium, while normalised passive tension of the immature myocardium is greater than that of the adult. The latter illustrates that immature myocardium is less compliant than adult myocardium. Numbers in brackets refer to numbers of animals studied. Each point and the vertical bars represent the mean $\pm$ SEM. L_{max} (see right hand end of abscissa) is a muscle length at which the greatest active tension was developed. (From Friedman WF: The intrinsic physiologic properties of the developing heart. *Prog Cardiovasc Dis* 1972;15:87–111, Figure 2.)

Figure 4-3 Longitudinal sections through the near central region of three myocytes from isolated rabbit hearts and their sarcomere shortening waveforms in response to field stimulation. **A**, An average-sized myocyte from the heart of a 3-week-old rabbit. **B**, A small-sized adult myocyte. **C**, An adult cell of average size. A sarcomere shortening waveform elicited from each cell is shown beneath its electron micrograph. Sarcomere length (SL) is plotted as a function of time (1 mM $[Ca^{2+}]$). Even the relatively small adult cell had a greater amount of sarcomere shortening and a faster rate of shortening than the average-sized immature cell. All cells are shown at identical magnification. (From Nassar R, Reedy MC, Anderson PAW: Developmental changes in the ultrastructure and sarcomere shortening of the isolated rabbit ventricular myocyte. *Circ Res* 1987;61:465–483, Figure 1.)

constriction of the discordantly connected pulmonary trunk, left ventricular mass increases markedly within a few days.

Hyperplasia

During fetal and early neonatal life, division of cells is the primary mechanism by which myocardial mass increases.^{3,4,6} In response to the greater workload borne by the postnatal left ventricle, the population of myocytes increases during neonatal life more rapidly in than in the right. Of note, in the mammal, hyperplasia, or the process of cytokinesis, is thought to cease after the first month or so of neonatal life. Evidence for hyperplasia in the adult heart has been provided in the adult amphibian heart, nonetheless, and more recently in the mammalian heart. The extent to which these

mechanisms, which may involve resident cardiac stem cells in the adult, generate additional myocytes in the adult mammalian heart remains to be established.^{7–9} The potential for division of myocytes, or generation of myocytes from stem cells, and the mechanisms underlying this process are, at present, topics of great interest and debate because of the need to develop new therapies for the failing heart.^{10,11}

Hypertrophy

Increasing size of the cardiac myocytes, or physiological hypertrophy, becomes the major mechanism through which ventricular mass increases after a few months of postnatal life^{3,4} (Figs. 4-3 and 4-4). The stimulus is the normal developmental increase in mural stress and work.^{12,13} This process is also present prenatally. Excessive pressure overload will induce hypertrophy, in addition to hyperplasia, in the fetal heart.¹⁴

The developmental process that results in physiological hypertrophy is associated with changes in the shape and size of the cardiac myocytes (Figs. 4-3 to 4-5). For example, the average length of the cardiac myocyte in the newborn rat is approximately 20 μ m, while that of the 11-day-old rat is 45 μ m.⁴ Only an increase of one-fifth in cross sectional area accompanies this doubling of cell length. The immature cardiac myocyte changes from being relatively ovoid to the long tetrahedral shape of the adult myocyte (see Fig. 4-3). A further postnatal increase in cell length is seen in the adult heart, with cell lengths of 150 μ m and longer being achieved in the mammal, and more than 300 μ m in the bird. The cross sectional minor diameter increases from 10 to 20 μ m following birth in the

Figure 4-4 The size and complexity of shape of cardiac myocytes increases with development. Cross-sections through widely separated levels of a myocyte isolated from an adult heart (**A–C**) and a myocyte isolated from the heart of a 3-week-old rabbit (**D–F**). (From Nassar R, Reedy MC, Anderson PAW: Developmental changes in the ultrastructure and sarcomere shortening of the isolated rabbit ventricular myocyte. *Circ Res* 1987;61:465–483, Figure 2.)

Figure 4-5 Longitudinal sections from single isolated myocytes: an adult myocyte (A) and a myocyte from a 3-week-old rabbit (B). The cell shape and myofibril organisation relative to the mitochondria and nuclei differ markedly at the two stages of development. The myofibrils of the neonatal myocyte are restricted to the subsarcolemmal region, while those of the adult are ranged in layers across the width of the cell. The second nucleus of the adult cell lies just out of view. (From Nassar R, Reedy MC, Anderson PAW: Developmental changes in the ultrastructure and sarcomere shortening of the isolated rabbit ventricular myocyte. *Circ Res* 1987;61:465–483, Figure 5.)

mammal² (see Fig. 4-4). These developmental changes are likely to have functional consequences, for example, the greater contribution of trans-sarcolemmal movement of calcium to the systolic $[Ca^{2+}]_i$ transient in the immature myocyte versus the greater contribution of calcium release from intracellular stores to be $[Ca^{2+}]_i$ transient in the adult myocyte (Fig. 4-6). The greater contribution of trans-sarcolemmal calcium to the $[Ca^{2+}]_i$ transient in the immature myocyte may be reflected in the apparent great sensitivity of the infant heart following surgery to an increase in concentration of calcium in the plasma.

REGULATION OF CYTOSOLIC CALCIUM

The cascade underlying cardiac contraction is initiated by depolarisation of the transmembrane potential. Voltage-gated calcium channels are activated, extracellular calcium enters the myocyte, and calcium is released from intracellular stores into the cytosol.^{15,16} The effects on sarcomeric function that follow from the systolic increase in cytosolic concentrations of $[Ca^{2+}]_i$ in the cytosol will be described in the section of the chapter devoted to the sarcomere. During diastole, $[Ca^{2+}]_i$ is about 100 nM, about 1/10,000 of extracellular calcium. The electrochemical gradient for entry of calcium is opposed primarily by the sarcolemmal Ca^{2+} TPase, a system with high affinity but low capacity that regulates resting or diastolic $[Ca^{2+}]_i$.

Figure 4-6 Regional changes in $[Ca^{2+}]_i$ in a newborn (A and B) and an adult (C and D) rabbit myocyte. A, Outline of a newborn (1-day-old) rabbit myocyte and the position of the scan line for the confocal microscope that was scanned repeatedly to monitor the rise and fall of $[Ca^{2+}]_i$ during systole and diastole, using a fluoroprobe (fluo 3). The $[Ca^{2+}]_i$ transients (yellow) of two contractions are illustrated in B. B, A three-dimensional reconstruction of the scan line. The direction of the arrow indicates time. The edges of the cell (the sarcolemma) are on the left and right sides of the image. The subsarcolemmal $[Ca^{2+}]_i$ increases before and more rapidly than $[Ca^{2+}]_i$ in the center of the cell, supporting the importance of trans-sarcolemmal influx of $[Ca^{2+}]_i$ during activation in the immature cell. C, Outline of an adult cell and position of the scan line for the confocal microscope that was repeatedly scanned to monitor the increase and fall in $[Ca^{2+}]_i$ during systole and diastole. D, Similar to B, the three-dimensional reconstruction of the time course of $[Ca^{2+}]_i$ during two sequential contractions. Unlike the newborn myocyte, $[Ca^{2+}]_i$ appears to rise uniformly across the entire width of the adult myocyte, illustrating the importance of CICR that follows from the T-tubular system and its calcium release units (see text). (From Haddock PS, Coetzee WA, Cho E, et al: Subcellular $[Ca^{2+}]_i$ gradients during excitation contraction coupling in newborn rabbit ventricular myocytes. *Circ Res* 1999;85:415–427.)

The L-type calcium channel, the dihydropyridine receptor, is the primary source for entry of calcium into the adult human cardiac myocyte.¹⁷ With depolarisation, the L-type calcium channel is activated, and influx of calcium occurs (Fig. 4-7). Following activation, and during the contraction, the channel closes as a consequence of an increase in $[Ca^{2+}]_i$, and further depolarisation, a feedback loop that limits the calcium current (I_{Ca}). Phosphorylation of the L-type calcium channel, secondary to β -adrenoreceptor stimulation, increases the calcium current. Another calcium channel, the T-type calcium channel, which is expressed in the embryonic heart, is activated at a more negative potential.^{18,19}

Exchange of calcium for sodium across the sarcolemma, through the Na^+Ca^{2+} exchanger, can occur in both directions^{15,20} (see Fig. 4-7). This exchange of three sodium molecules for one calcium molecule is energy dependent. The direction of the exchange of sodium and calcium through the exchanger is based on its reversal potential. At more positive membrane potentials and higher $[Na^+]_i$, influx is favoured through the exchanger. In some species, this exchanger may provide an amount of calcium to the

Figure 4-7 A, Schematic representation of the basis of the rise and fall in cytosolic calcium concentration $[Ca^{2+}]_i$ during a contraction. With activation, the voltage-dependent calcium channels located in the T-tubule open, and the inward movement of calcium results in release of calcium from the JSR (see Fig. 4-8). The calcium that is released from the CSR and JSR was obtained through LSR uptake of calcium during the previous contraction. Trans-sarcolemmal movement of calcium is also a product of the Na^+Ca^{2+} exchanger. Because of its voltage dependence, this exchanger functions primarily as an efficient mechanism for removing calcium from the cell. The Na^+Ca^{2+} exchanger also functions in reverse, providing a mechanism for entry of calcium into the cell during systole. B, The generally accepted model of calcium-induced calcium release (CICR) is illustrated. With activation, calcium movement through the L-type calcium channels increases the local $[Ca^{2+}]_i$ near the ryanodine receptor (RyR, the SR calcium-release channel). The local increase in calcium induces release of calcium from the JSR, markedly amplifying the increase in $[Ca^{2+}]_i$. CSR, corbular sarcoplasmic reticulum (see text); JSR, junctional sarcoplasmic reticulum; LSR, longitudinal sarcoplasmic reticulum; T, T-tubule.

systolic $[Ca^{2+}]_i$ transient similar to that provided by the L-type calcium channel. When the membrane potential is more negative, and $[Ca^{2+}]_i$ is higher, removal of calcium from the cell is favoured, helping restore $[Ca^{2+}]_i$ to diastolic levels. Operating in this mode, the exchanger demonstrates its role as a system with low affinity and high capacity, designed to deal with the intracellular loads of calcium.

The sarcoplasmic reticulum is the major intracellular site of release of calcium needed to support the $[Ca^{2+}]_i$ transient.¹⁵ The reticulum contains specialised components, namely the junctional, corbular, and longitudinal components² (Figs. 4-7 to 4-9). The junctional and corbular components contain calcium-binding calsequestrin, with 40 calcium molecules bound to each calsequestrin molecule, triadin, junctin, and the ryanodine receptors, known as the RyRs, and representing the calcium-permeable ion channel of the reticulum. Corbular reticulum is not associated with the sarcolemma, while the junctional part is morphologically and functionally coupled to the transverse-tubules (see Fig. 4-8), forming dyads with the T-tubule sarcolemma, and peripheral couplings with the surface sarcolemma. The junctional and corbular components are located at the level of the Z-disc, where T-tubules are located. The T-tubular system, providing sarcolemmal extensions from the surface of the myocyte to deep within its core, is acquired with development, and is present in adult mammalian ventricular myocytes (see Figs. 4-7 and 4-8).

Entry of calcium into the cell triggers calcium-induced release from the sarcoplasmic reticulum (see Fig. 4-7). The calcium release units that support the systolic $[Ca^{2+}]_i$ transient are specialised junctional domains of the reticulum containing the L-type calcium channel, dihydropyridine receptors of the surface sarcolemma, and that of the T-tubule, the RyRs, triadin and junctin, and calsequestrin, the high capacity-low affinity calcium binding protein.²¹ The latter four molecules form a supramolecular quaternary complex in the junctional and corbular parts of the sarcoplasmic

reticulum.¹⁶ Junctin binds calsequestrin within the calcium release units, but is not required for its localisation to the junctional and corbular components.²² Junctin, also, regulates contractility but is not required for contraction.²³ The predominant ryanodine receptor in the heart is RyR2. The central role of trans-sarcolemmal influx of calcium in initiating calcium-induced release of calcium is evidenced by the effect of removing extracellular calcium. Activation of membranes in the absence of extracellular calcium does not result in excitation-contraction coupling. There is no $[Ca^{2+}]_i$ transient, and the myocyte fails to contract.

The close structural relationship between the junctional component of the sarcoplasmic reticulum and the L-type calcium channel, located in the sarcolemmal T-tubules, ensures that voltage-dependent opening of the L-type channel, and the associated flow of extracellular calcium into the cytosol, produces a very high $[Ca^{2+}]_i$ ryanodine receptor (see Fig. 4-7). In response to the increase in $[Ca^{2+}]_i$ with excitation, the ryanodine receptors are activated throughout the myocyte, and calcium flows into the cytosol from the sarcoplasmic reticulum, amplifying the effect of the L-type calcium channel current on the $[Ca^{2+}]_i$ transient.^{24,25} The ryanodine receptors are, also, a scaffolding protein. The associated molecules in the release units, and associated kinases, phosphatases, and calmodulin are likely to modulate their function.^{16,26,27}

Cardiac relaxation follows the fall in the $[Ca^{2+}]_i$ transient to diastolic levels. Extrusion of calcium from the myocyte, and intracellular uptake of calcium, underlie this process. The major intracellular site of uptake is the longitudinal component of the sarcoplasmic reticulum (see Figs. 4-7 and 4-9). Although the mitochondria serve as a site for intracellular storage of calcium, they do not significantly contribute to the fall in the $[Ca^{2+}]_i$ transient. The longitudinal elements of the reticulum contain the sarcoplasmic version of calcium ATPase, known as SERCA, a transmembrane protein that translates calcium from the cytosol into the

Figure 4-8 Electron micrograph of an isolated adult myocyte illustrates the membranous systems important in the beat-to-beat regulation of $[Ca^{2+}]_i$. The sarcolemma and extracellular space are at the top of the illustration. The invagination of the T-tubule in the upper part of the illustration is marked by the arrow (upper left side of image). The LSR, the membranous system that enfolds the myofilaments and removes calcium from the cytosol through its calcium ATPase, is pointed out by the arrowheads. The CSR and JSR, the sites of calcium release that support the cardiac contraction, are pointed out by the small arrow.

lumen of the sarcoplasmic reticulum.¹⁵ Activity of SERCA is isoform dependent.²⁸ Of note, across development, cardiac myocytes express only SERCA2a. The longitudinal elements of the reticulum surround each sarcomere from Z-disc to Z-disc like a three-dimensional mesh, providing a system for rapid removal of the calcium bathed in the myofibrils (see Fig. 4-9). Calcium pumping is enhanced by $[Ca^{2+}]_i$ and decreased by $[Ca^{2+}]_i$ within the sarcoplasmic reticulum. Activity of SERCA is inhibited by phospholamban.²⁹ Phosphorylation of phospholamban in response to β -adrenoreceptor stimulation removes its inhibitory effect on the activity of SERCA, and leads to a greater uptake of calcium into the longitudinal sarcoplasmic reticulum, providing a larger pool of calcium for release through the ryanodine receptors in subsequent contractions.

In summary, the systolic $[Ca^{2+}]_i$ transient is driven by modulation of the L-type calcium current, SERCA activity, the volume, organisation, and content of calcium in the sarcoplasmic reticulum, the number and properties of the ryanodine receptors, the sodium calcium exchanger, and the extent to which calsequestrin is saturated with calcium. Altogether, they modulate the systolic $[Ca^{2+}]_i$ transient, provide the basis for the heart to vary its force of contraction from beat-to-beat, in other words the ability to modulate cardiac contractility. These processes underlie the increase in contractility that occurs with increase in heart rate, and those that follow from the introduction of an extrasystole. The extrasystole leads to greater content of calcium in the sarcoplasmic reticulum, allowing greater release of calcium, and a higher $[Ca^{2+}]_i$ transient in the post-extrasystolic contraction, and so post-extrasystolic potentiation (Fig. 4-10).

Figure 4-9 Longitudinal section of an isolated adult cell. The repetitive arrangement of CSR and LSR is typical of the mature myocyte. A myofibril passes slightly out of the section plane and reveals a ring of CSR components (black arrows) at each Z band and the network of LSR components (white arrows and braces) around each sarcomere. (From Nassar R, Reedy MC, Anderson PAW: Developmental changes in the ultrastructure and sarcomere shortening of the isolated rabbit ventricular myocyte. *Circ Res* 1987;61: 465–483, Figure 10.)

DEVELOPMENT AND REGULATION OF CYTOSOLIC CALCIUM

The $[Ca^{2+}]_i$ transient increases postnatally in the mammalian ventricular myocyte³⁰ (Fig. 4-11). In the immature heart, the $[Ca^{2+}]_i$ transient in response to excitation-contraction coupling has a greater dependence on trans-sarcolemmal influx of calcium³¹ (see Fig. 4-6). Developmental changes in the sarcoplasmic reticulum, the calcium release units, constituted in its specialised junctional domains,^{2,22} and expression of the sodium calcium exchanger, are all pertinent to this observation.^{32,33}

The organisation, differentiation, and relative volume of the sarcoplasmic reticulum increase with development, and the size and frequency of the specialised couplings with the surface and T-tubular sarcolemmal units that contain the elements for release of calcium increase with development.^{21,22} The T-tubular system is acquired with development in the mammalian ventricular myocyte. The relative volume of the cells comprising the sarcoplasmic reticulum increases during late gestation, and following birth,^{2,34} and the structure of the release units changes with development. In the immature myocyte, ryanodine receptors extend from the corbular component onto the surface of the longitudinal elements, while calsequestrin, located within the lumen of the corbular component in the adult, extends into the lumens of the longitudinal elements in the neonatal myocyte (Fig. 4-12). The expression and targeting of calsequestrin to the junctional and corbular

Figure 4-10 Postextrasystolic potentiation: effect of introducing an extrasystole on sarcomere shortening in a cardiac myocyte isolated from an adult rabbit heart. The previous contraction at the regular pacing rate (blue circles), the extrasystole (red triangles), and the postextrasystolic contraction (black squares) are superimposed. The amount and velocity of sarcomere shortening in the extrasystole are smaller than for the previous contraction at the regular pacing rate and are greater for the subsequent extrasystolic potentiated contraction.

components is an early embryonic event that is followed by the expression of junctin and triadin. The developmental localisation of calsequestrin within the junctional and corbular components may be related to a marked postnatal increase in expression of junctin, and its binding of calsequestrin within the specialised region of the sarcoplasmic reticulum.³⁵ The fixed structural relation between the corbular components and the Z-disc are acquired postnatally (compare Figs. 4-9 and 4-12) in mammals that are not born ready to flee the nest as neonates. The lack of differentiation of the sarcoplasmic reticulum, and its ordered relation with other membranes in the immature myocyte, prevents the close coupling of the L-type calcium channel and the ryanodine receptors. This is likely, in the presence of a lower L-type calcium current density, to contribute to the slower rates of rise and lower peak systolic $[Ca^{2+}]_i$ transient in the immature myocyte³⁰ (see Fig. 4-11).

Function of the sarcoplasmic reticulum also changes with development as measured by increases in activity and

efficiency of SERCA. These developmental changes in activity and efficiency will result in a more effective uptake of calcium by the sarcoplasmic reticulum, providing more calcium to be released during a subsequent contraction and, so, a developmental increase in the range over which the force of contraction can be modulated.

The developmental changes in the structural and biochemical properties of the sarcoplasmic reticulum are reflected in interventions that affect release of calcium by the ryanodine receptors. Ryanodine itself, which inhibits release of calcium by the receptors, does not affect the development of force by fetal myocardium, including that of humans. Within a few days following birth, however, ryanodine markedly attenuates the force of contraction.^{36,37} Caffeine, which increases release of calcium by the receptors, has little effect on neonatal myocardium, while enhancing contractility in the adult. These findings support the importance of the developmental acquisition of the components underlying calcium-induced release of calcium, and the consequent decreased dependence of the adult heart on trans-sarcolemmal influx of calcium (see Fig. 4-6).

The greater role of contribution of the sarcoplasmic reticulum to the $[Ca^{2+}]_i$ transient in the adult heart is evidenced by post-extrasystolic potentiation and the restitution of contractility (see Figs. 4-10 and 4-13). Post-extrasystolic potentiation increases with maturation.³⁸ In addition, the restitution of contractility following a contraction (see Fig. 4-13) is also acquired with maturation.^{2,38} Altogether, these findings demonstrate that the developmental increase in the amount, organisation, and structure of the sarcoplasmic reticulum and the calcium release units have a fundamental role in the developmental increase in the peak $[Ca^{2+}]_i$ transient in response to the L-type calcium current with activation.

There are two calcium channels expressed in the myocardium during development, the T-type and the L-type, the latter being dihydropyridine-sensitive. Early in development, a T-type calcium current is present, while in the adult heart, very little, if any, T-type calcium channel is expressed.¹⁸ The developmental changes in the L-type calcium current density are more complex. In general, it increases with development (see Fig. 4-11). This increase may be related to an increase in the number of channels, or to differential expression of the α - and β -subunit isoforms.

Figure 4-11 Comparison of systolic $[Ca^{2+}]_i$ transients and L-type calcium currents from 3-week-old and adult rabbit ventricular myocytes. **A**, Calcium transients from the 3-week-old (red waveform) show much smaller transients than the adult (blue waveform). Diastolic levels were 155 and 103 nmol/l respectively. **B**, L-type calcium currents (I_{Ca}) from the 3-week-old (red waveform) show a significantly smaller current than the adult (blue waveform) myocyte. **C**, I_{Ca} -voltage relations from a 3-week-old (capacitance 61 pF, red symbols) and an adult (capacitance 109 pF, blue symbols) myocyte showing a significantly lower I_{Ca} density in the immature myocyte.

Figure 4-12 Longitudinal section of a myocyte isolated from the heart of a 3-week-old rabbit. Contrast the looser organisation of the CSR (black arrows) and LSR (arrowheads) with the tightly arranged adult arrangement (see Fig. 4-9). Also of note are the broader connections between the corbular and longitudinal components of the immature cell (small double arrows) and the extension of the ryanodine receptors over the LSR. Cell surface is to the left. (From Nassar R, Reedy MC, Anderson PAW: Developmental changes in the ultrastructure and sarcomere shortening of the isolated rabbit ventricular myocyte. *Circ Res* 1987;61:465–483, Figure 11.)

Importantly, the developmental increase in the L-type calcium current density provides a greater trigger for calcium-induced release of calcium.

The activity and expression of the sodium calcium exchanger increase during fetal life to a plateau, and subsequently fall rapidly during postnatal development.³³ The exchanger, working in a reverse mode, provides an important mechanism for influx of calcium to support the systolic $[Ca^{2+}]_i$ transient in the neonatal myocyte.³⁹ Working in the forward mode, the exchanger provides an effective mechanism for removal of calcium from the cytosol, bringing about relaxation.¹⁵ Its effectiveness in removing calcium from the cell in association with a decreased uptake of calcium by the immature sarcoplasmic reticulum may result in little calcium being taken up by the immature sarcoplasmic reticulum, and so decreasing in the immature myocyte the calcium available for release from the sarcoplasmic reticulum in subsequent contractions.

Sodium potassium ATPase, a pump that regulates transsarcolemmal concentrations of the sodium and potassium ions, indirectly affects calcium within the cell. Cardioactive glycosides, for example digoxin, selectively bind to and inhibit the sodium potassium ATPase. Inhibition of this enzyme is thought to lead to elevation of sodium ions, with consequent increase in cellular and sarcoplasmic reticulate calcium via the exchanger.⁴⁰ Of note, other mechanisms for glycoside-induced enhancement of contractility have

Figure 4-13 A comparison of restitution of sarcomere shortening in extrasystole between an immature (A, red) and an adult (B, blue) cell. The test interval is the time between application of the extrasystolic stimulus and the previous regular stimulus. A, In the immature cells, the earliest extrasystole that could be elicited exhibited the same amount of sarcomere shortening as the contraction at the regular rate. The absence of restitution in the immature myocyte is consistent with its sarcoplasmic reticulum being unable to modulate cytosolic calcium concentration, and so sarcomere shortening. B, In the adult cell, restitution was gradual (the dotted line is monoexponential curve, time constant 0.4 sec) demonstrating the ability of the adult myocyte to regulate its $[Ca^{2+}]_i$, and so sarcomere shortening over a broad range of calcium concentration and amounts of sarcomere shortening. (From Nassar R, Reedy MC, Anderson PAW: Developmental changes in the ultrastructure and sarcomere shortening of the isolated rabbit ventricular myocyte. *Circ Res* 1987;61:465–483, Figure 4.)

been suggested, including direct activation of ryanodine receptors, and increased selectivity by calcium of sodium channels.⁴¹

Developmental changes have been found in the relative amount of the activity of the enzyme, and expression of its isoforms. Tissue-specific developmentally regulated and differentially localised expression of the α -subunit isoforms, the catalytic subunit, and differential effects of a β -subunit isoforms on affinity for sodium suggests that these isoforms have distinct roles.^{42–44} These isoforms have different sensitivities and affinities for binding to cardiac glycosides. Myocardial contractility in the immature heart is positively affected by digoxin.^{45,46} The differential expression of the isoforms, and the developmental regulation of this system, suggest that, in the human, α -subunit isoforms may contribute to maturational differences in the response to digoxin.

THE SARCOMERE

The sarcomere, the force-producing unit of the heart, is present at all stages of development. It is made up of a lattice-like highly organised arrangement of thick and thin filaments (Fig. 4-14A and B). The thick filament is a bipolar structure about 1.5 μ m in length containing myosin heavy chain and multiple accessory proteins (see Fig. 4-14B). Myosin is asymmetrically shaped, and is made up of two heavy chains and two pairs of associated light chains.⁴⁷ The heavy chains form two globular domains, the heads at one end of the molecule containing ATPase and a long rod-like coiled-coil domain. Molecules of the heavy chain are

Figure 4-14 The sarcomere. **A**, A longitudinal section through the sarcomere demonstrates the interdigitation of the myosin-containing thick filaments (blue) with the actin-containing thin filaments. A cross-section of the sarcomere at x shows only thick filaments, demonstrating the absence of any overlap of thick and thin filaments. The cross-section at y demonstrates the hexagonal array of thin filaments around the thick filaments that enable actin-myosin interaction and cross-bridge formation. The cross-section at z demonstrates that no thick and thin filament overlap is present at this sarcomere length, only thin filaments are seen. Note the thin filaments are attached to the Z-disc (z arrows) as are the titin filaments (see Fig. 4-16). **B**, The left hand part of a sarcomere. The thick filaments of the sarcomere contain dimers of myosin (blue). The protruding myosin heads contain the ATPase and actin-binding sites. The attachment of the myosin heads to actin in the presence of ATP results in force production and translocation of the actin-containing thin filaments towards the centre of the sarcomere (see arrow x in (A)).

made up of homodimers or heterodimers of cardiac α - and β -units. The α -homodimers have the highest activity of ATPase, the α - β heterodimers have low immediate activity, and β -homodimers have the lowest activity. The long rod domains form the filament backbone of the thick filament, while the heads lie on the surface of the thick filament in a position that allows formation of strong cross-bridges with actin monomers in the adjacent thin filament.^{48,49} Production of force, and sarcomeric shortening, require cyclic binding of the myosin heads to actin in the presence of calcium and adenosine triphosphate. Adenosine triphosphate is converted by the myosin ATPase into chemical energy, which is then converted into mechanical energy, moving the myosin head on actin, generating force and so sarcomeric shortening, and ejection of blood from the ventricle. Sarcomeric length affects the number of sites of actin available for binding with myosin. Based on the length of the thick filaments, and the central region of the thick filament that is bare of myosin heads, the optimum sarcomeric length for interaction between actin and myosin, and formation of cross-bridges, is from 2.0 to 2.2 μm (Fig. 4-15). The length of the sarcomere also modulates the sensitivity of myofilamentous development of force to calcium through increasing affinity to troponin C, with an increase in sarcomeric length, as discussed below (see Fig. 4-18).

The accessory proteins in the thick filaments include an essential light chain, and a regulatory light chain, that are associated with each myosin head.^{50,51} Phosphorylation of the regulatory light chain increases the sensitivity of myofilamentous development of force to calcium⁵² (see Fig. 4-18). Other accessory proteins are myosin binding protein C, myomesin, m-protein, and titin^{53–55} (Fig. 4-16). The C binding protein modulates assembly of myosin, and its interaction with actin, stabilises the thick filaments, and interacts with actin. In response to β -adrenoreceptor stimulation, the single cardiac isoform of the C binding protein is phosphorylated by cyclic-AMP-dependent protein kinase A.⁵⁶ Titin, a long elastic protein, with a molecular

weight of nearly 3000 kDa, keeps the thick filaments of the sarcomere centred between the Z-discs, maintains the integrity of the sarcomere, and supports, in part, its passive tension.⁵⁵ The titin filaments extend from the Z-discs, independent of the thin filaments, and attach to and continue along the thick filament, ultimately extending to and attaching to the next Z-disc (see Fig. 4-16).

The thin filaments contain a backbone of coiled-coil of filamentous actin wrapped by a coiled-coil of tropomyosin, which is regularly decorated with the three subunits troponin I, troponin C, and troponin T⁵⁷ (Fig. 4-17). At the nanomolar diastolic $[\text{Ca}^{2+}]_i$, troponin I inhibits the interaction between actin and myosin, and tropomyosin sterically interferes with the site of binding of myosin on actin. Binding of calcium to troponin C with the systolic increase $[\text{Ca}^{2+}]_i$

Figure 4-15 The extent of overlap of the thick and thin filaments of the sarcomere (see Fig. 4-14) alters the number of potential myosin-actin interactions. The greatest number of cross-bridges is found when the overlap of the thick and thin filaments is optimal. The commonly given sarcomere length (S_1) for this optimum overlap is 2.0 to 2.2 μm . At longer sarcomere lengths, the number of potential actin-myosin interactions decreases until the sarcomere length is so long (i.e., greater than 3.6 μm) that no active force is developed.

Figure 4-16 Domain structure of I-band titin isoforms in a cardiac sarcomere. The I-band portion of titin contributes to myocardial passive stiffness and the elasticity (see Figure 4-21). Titin isoform expression changes with development. The expression of N2BA falls, and the expression of N2B and other smaller isoforms increases. The longer and N2BA isoform is more compliant than N2B. In the adult human heart, the ratio of N2B:N2BA is approximately 70:30. The elastic region of titin encompasses three structurally distinct segments: serially linked tandem-Ig domains, the PEVK-domain, and the N2B-unique sequence. Two principal isoforms, N2B and N2BA, are co-expressed in the same half-sarcomere and may extend independently. The length differences between the two main cardiac isoforms are caused by alternative splicing of the mid-Ig domains and PEVK exons. For clarity, the sarcomere model (bottom) does not show the real number of titin/connectin domains known from sequence studies. (From Opitz CA, Linke WA: Plasticity of cardiac titin/connectin in heart development. *J Muscle Res Cell Motil* 2005;26:333–342.)

removes the inhibitory effect of troponin I, and results in a change in the physical interaction and spatial orientation among troponin C, troponin I, actin, troponin T, and tropomyosin. This interaction results in a shift in tropomyosin on the thin filament, exposing the site of binding of myosin on actin. The structure of tropomyosin gives it segmental flexibility, and the ability to shift its position. A tristate model of thin filamentous activation is based on the observation of three positions of tropomyosin on actin. The blocked state prevents strong binding of myosin to actin, the closed state in the presence of increased calcium does not fully block interaction, while the myosin-induced, or active, state of the thin filament permits strong interactions.⁵⁸ This simple on/off system is modulated by troponin T. The result is the physiologically critical dependence of calcium on activity

Figure 4-17 The thin filament comprises a coiled-coil of actin wrapped by a coiled-coil of tropomyosin. A troponin complex is regularly attached to the tropomyosin filament. The ratio is seven actins, one tropomyosin, and one troponin complex per functional unit (see text). The troponin complex contains the inhibitory protein troponin I (TnI), troponin C (TnC), which when bound to calcium removes this inhibition, and troponin T (TnT) that binds the complex to tropomyosin overlapping the amino-carboxyl regions of adjacent tropomyosin molecules. TnT is essential for calcium-dependent myofibrillar ATPase activity and force development.

of myofibrillar adenosine triphosphatase, and development of force^{57,59,60} (Fig. 4-18A and B).

The sensitivity of development of force to calcium provides the basis for myocardial contractility being modulated by $[Ca^{2+}]_i$. Different levels of active force develop in the presence of different $[Ca^{2+}]_i$. This relation is illustrated in Figure 4-18. Below 100 nmol $[Ca^{2+}]_i$, no force is developed. With increasing concentrations, there is a steep increase in development of force over a narrow range. Finally, the active development of force plateaus at higher concentrations. The steepness of the relationship demonstrates the presence of cooperative interactions that amplify the effect of binding of calcium to the solitary site of binding on cardiac troponin C, and so the number of cross-bridges that are formed.⁵⁷ These cooperative interactions follow, in part, from the functional groups that are made up of seven actins, one tropomyosin, and one troponin complex (see Fig. 4-17). In addition, strong-binding cross-bridges increase cooperativity. These cross-bridges appear to have allosteric effects that result in spread of activation within and between the functional groups. The dominance of myofilamentous related processes on development of force is demonstrated by the $[Ca^{2+}]_i$ transient returning to diastolic levels prior to the fall in force, a consequence of the off-rate of release of calcium from cardiac troponin C being slower than the rate of removal of calcium from the cytosol. Thus, strong cross-bridges, generated in response to binding of calcium cardiac troponin C, maintain activation of the thin filament and active development of force.

Modulation of the sensitivity of development of force to calcium provides an important mechanism underlying the minute-to-minute modulation of cardiac contractility. A shift in the relation between force and pCa changes the sensitivity of development of force (see Fig. 4-18B, where pCa is the negative log of $[Ca^{2+}]_i$): The result is the same $[Ca^{2+}]_i$ producing a greater increase in force, seen in the shift in the force-pCa relation to lower $[Ca^{2+}]_i$ (see Fig. 4-18B).

Figure 4-18 The sigmoidal relation describes the sensitivity of the myofilaments to calcium, seen here as the effect of calcium concentration on myofilament force (F) production. **A**, Calcium concentration is illustrated as pCa^{2+} , the negative log of $[Ca^{2+}]$. At low $[Ca^{2+}]$, no force is developed. Over the physiological range of $[Ca^{2+}]$ induced by activation and CICR, a steep relationship between force and $[Ca^{2+}]$ exists. At still higher $[Ca^{2+}]$, no greater force development occurs. **B**, The sensitivity of myofilaments to calcium is dependent on factors such as sarcomere length and post-translational modifications of the contractile proteins. When sarcomere length is increased, the relation is shifted to the left toward lower $[Ca^{2+}]$ (yellow arrow). In other words, the myofilaments become more sensitive to calcium. This effect of sarcomere length is in addition to the cross-bridge interactions described in Figure 4-15. Phosphorylation of cardiac TnI, in response to β -adrenergic stimulation, shifts the relation towards higher $[Ca^{2+}]$ (blue arrow) decreasing the sensitivity of the myofilaments to calcium.

Calcium-calmodulin dependent phosphorylation of the regulatory myosin light chain, and switch in expression of the myosin heavy chain isoforms, enhance myofilamentous sensitivity to calcium. Protein kinase C phosphorylation of cardiac troponin I and cardiac troponin T also modulates the sensitivity of development of force to calcium.⁶¹ Acidic pH decreases the myofilamentous sensitivity to calcium. It also depresses the peak force of contraction. The result of this effect of acidic pH is that the same systolic $[Ca^{2+}]_i$ transient will elicit a weaker cardiac contraction.

Increasing muscular length increases the sensitivity of the myofilaments to calcium⁶² (see Fig. 4-18). At longer sarcomeric lengths, cardiac troponin C has a greater affinity for calcium. Although this property is seen in both skeletal muscle and cardiac muscle, the increase in sensitivity to calcium with an increase in sarcomeric length is greater in cardiac muscle. The positive effect of sarcomeric length on myofilamentous sensitivity to calcium provides a molecular basis for the Frank–Starling relation.

DEVELOPMENT AND THE SARCOMERE

The sensitivity of myofilamentous development of force to calcium and the effect of acidic pH on this sensitivity change with development. Across phyla, the myofilamentous development of force is more sensitive to calcium in the fetal and neonatal heart as compared to the adult heart.^{63,64} In contrast, acidosis has a greater negative effect on these processes in the adult compared to the fetal and neonatal situations.^{65,66} Altogether, these developmental changes appear to be teleologically appropriate. The peak cytosolic transient for calcium is lower in the immature myocyte (see Fig. 4-11), requiring a greater sensitivity of the myofilaments to calcium to induce a comparable force of contraction for a given concentration. The greater resistance of the immature heart to acidosis, also, seems appropriate given that episodes of acidosis are likely to occur during perinatal life.

The developmental switch in expression from slow skeletal to cardiac troponin I has an important effect on the extent to which acidic pH negatively affects myofilamentous function.⁶⁷ In the human, developmental pull in slow skeletal troponin I takes place during fetal life, and the first

years of postnatal life.^{68,69} The expression of the slow skeletal form in the immature heart provides a protective effect against perinatal acidosis. Development of force by myofilaments containing the slow skeletal form is more resistant to acidosis than that of myofilaments containing the cardiac version.

The complexity of the differential effects of these different forms of troponin I on the sensitivity of the myofilaments to calcium at different stages of development is reflected in several ways. First, myofilaments containing the slow skeletal form are more sensitive to calcium, as measured by active development of force, while being less sensitive to acidic pH. Second, cardiac myocytes expressing the slow skeletal form have impaired relaxation, and left ventricles expressing this form have slowed diastolic relaxation.⁷⁰ Third, expression of the cardiac form confers onto the myofilaments a more positive effect of increasing their length on myofilamentous calcium, and so enhances the Frank–Starling relation.⁷¹ Fourth, phosphorylation of the cardiac form dependent on cyclic adenosine triphosphate, through stimulations of β -adrenoreceptors, decreases the sensitivity of the myofilaments to calcium,⁷² blunting markedly the effect of increasing sarcomeric length on increasing myofilamentous sensitivity to calcium. The physiological importance of such phosphorylation of the cardiac form on sensitivity to calcium is a more rapid relaxation of myocardial contraction. This more rapid relaxation is important given the stimulation of the β -adrenoreceptors increases in the peak of the $[Ca^{2+}]_i$ transient, development of force, and heart rate. In the absence of the more rapid relaxation that follows from this phosphorylation, the increase in heart rate induced by stimulation of β -adrenoreceptors would be associated with an inappropriate decrease in diastolic filling time, and a compromise in ventricular filling, negatively affecting stroke volume. In contrast, stimulation of β -adrenoreceptors has no effect on the slow skeletal form of troponin I, making the sarcomere in the developing heart less sensitive to the effects of such stimulation, and so potentially superimposing a compounding effect on the positive effects of stimulation on heart rate and the $[Ca^{2+}]_i$ transient, while maintaining the Frank–Starling relation in a positive fashion.

Figure 4-19 Myocardial contractility increases with development. Relationships between the extent (A) and velocity (B) of shortening and developed tension (i.e., afterload) of myocardium isolated from fetal and adult sheep (blue, adult data; red, fetal data). Both reflect the ability of the myocardium to generate tension. Fetal myocardium is not able to shorten with the same velocity and to the same extent as adult myocardium does when subjected to the same load. Each point and vertical bar represents the mean $\pm$ SEM. (From Friedman WF: The intrinsic physiologic properties of the developing heart. *Prog Cardiovasc Dis* 1972;15:87–111, Figure 3.)

Developmental switching in the expression of the isoforms of cardiac troponin T, also, affects the sensitivity of myofilamentous development of force to calcium.^{30,63} During development, the expression of the two longest and most acidic isoforms decreases, while that of the two shorter and less acidic ones increases.⁷³ The calcium sensitivity of the myofilaments is greatest in the presence of the two longest isoforms.⁷⁴ I have already emphasised that the calcium transient is lower in the neonatal than in the adult myocyte³⁰ (see Fig. 4-11). Furthermore, the expression of the longer isoforms in the developing heart compensates for the lower calcium transient in the immature heart. The expression of the isoforms of troponin I modulates the effects of the cardiac isoforms of troponin T on the sensitivity of the myofilaments to calcium. The slow skeletal form expressed in the immature heart enhances the positive effect of the longer isoforms of cardiac troponin T, further compensating for the smaller calcium transient in the immature heart, and helping support its function.⁷⁵

The β - and α -isoforms of tropomyosin have a differential effect on the sensitivity of the myofilaments to calcium, and also undergo changes in expression with development. In the rodent, α -tropomyosin essentially replaces β -tropomyosin in the adult heart.⁷⁶ In contrast, in the human, β -tropomyosin expression increases by half from the fetus to the adult.⁷⁷ Myofilaments containing β -tropomyosin have greater sensitivity to calcium, so that the developmental switch in the rodent to α -tropomyosin will lead to a decrease in sensitivity of development of force to calcium. Consistent with this effect, ventricles expressing β -tropomyosin have decreased rates of ventricular diastolic relaxation as compared to those expressing α -tropomyosin.⁷⁸ In contrast, in the human, the developmental increase in expression of β -tropomyosin could have a positive effect on the sensitivity of myofilamentous development of force to calcium.

The velocity of myocardial shortening increases with development. These changes are well correlated

with activity of myofibrillar adenosine triphosphatase¹ (Fig. 4-19). The developmental switch in expression from the β to the α variant of myosin heavy chain in the rat heart has led to the correlation of developmental changes in shortening velocity to expression of the isozymes of myosin heavy chain. In the human, it is the β form that is expressed predominantly across maturation from fetal life through senescence, and also in the presence of hypertrophy and cardiac failure. Consequently, in the human, maturational changes in expression of isozymes are not likely to contribute to the developmental increase in myocardial contractility. There is a complex developmental pattern of expression of the α -isoform of actin.^{79–81} The smooth muscle variant is expressed during cardiac embryogenesis. Subsequently, the skeletal and cardiac forms are expressed differentially with development in a species-dependent manner. In the rodent, the skeletal form is expressed in the fetus, and the cardiac form in the adult. In contrast, in human myocardium, expression of cardiac α -actin is highest during fetal development, while expression of the skeletal variant is equal to or higher than the cardiac form in the adult heart.⁸² The skeletal, and cardiac forms of α -actin differ by only a few residues. The basis for the differences in expression of the isoforms between species, and the consequences of these different patterns on function and organogenesis, remain to be determined.

THE MYOCYtic CYTOSKELETON

The cytoskeleton is the complex meshwork of structural proteins that gives the cell its shape and organisation. In addition to the myofibrils, the microtubules, and intermediate filaments, made up of desmin, there are other major components. They connect the Z-discs to the sarcomeres, the myofibrils one to another, and the myofibrils to the T-tubules, mitochondria, and nuclei (Fig. 4-20). Myofibrils that lie just underneath the sarcolemma are

Figure 4-20 The relation of the Z-band to the sarcolemma and to the intermediate filaments in isolated adult cardiac myocytes. **A**, A longitudinal section shows two rows of myofibrils and mitochondria. The sarcolemma is on the right, and a nucleus is at the left. The sarcolemma appears fused with the Z-I area of the sarcomere at the *arrow*, the region of colocalisation of the cytoskeletal protein vinculin and the extracellular matrix protein-binding integrins. **B**, A cross-section of a comparable region of another adult cell. The density between the sarcolemma and the Z-I band area is frequently observed (*arrow*). **C**, The cytoskeletal attachment of the T-tubule to the Z-band is suggested by this image, in which the T-tubule profile maintains a close proximity to two Z-lines that are out of register (*arrow*). **D**, A slightly oblique longitudinal section of a myocyte from the heart of a 3-week-old rabbit illustrates a ring of intermediate filaments surrounding the Z-line (*arrow*). (From Nassar R, Reedy MC, Anderson PAW: Developmental changes in the ultrastructure and sarcomere shortening of the isolated rabbit ventricular myocyte. *Circ Res* 1987;61:465–483, Figure 9.)

attached to the sarcolemma at the Z-disc by structures called costameres, which are formed from vinculin, another cytoskeletal protein (see Fig. 4-20).⁸³ Desmin-containing intermediate filaments, and the vinculin-containing costameres, together with titin, provide the passive properties of length and tension of the single cardiac myocyte, and contribute to the properties of the intact myocardium⁸³ (Figs. 4-21 and 4-22). This scaffolding of microtubules, intermediate filaments, and costameres underlies the integrated movement of the contractile apparatus, the intracellular membranous compartments, and the sarcolemma during contraction and relaxation in the adult myocyte.

The cytoskeletal proteins spectrin and ankyrin are located in the sarcolemma near the Z-disc, and extend along the sarcolemma from Z-disc to Z-disc. The spectrins and sarco-glycan complex are thought to play a role in maintaining cellular integrity and flexibility as components of the membrane cytoskeleton.⁸⁴ α -Actinin, a major component of the Z-disc in striated muscle, and β -spectrin, have a highly conserved amino-terminal actin-binding domain.⁸⁵ Through this domain, α -actinin provides an anchor for the sarcomeric thin filaments in the Z-disc.

Integrins are transmembrane receptors for the proteins within the extracellular matrix, for example collagen, fibronectin, and laminin. They colocalise with the cytoskeletal attachments to the sarcolemma.⁸⁶ Their receptors are dimeric, containing an α - and β -subunit with the β -subunits being associated with different sets of α -subunits.⁸⁶ The multiple α -subunits appear to confer ligand specificity, in that α_1 - and α_2 -subunits have affinity for interstitial collagens, collagen type IV, and laminin, while the α_3 -subunit interacts with fibronectin. These integrins are localised to sarcolemmal regions adjacent to the Z-discs, providing sites of attachment of collagen to the sarcolemmal Vinculin, the cytoskeletal protein that attaches the Z-discs to the sarcolemma, colocalises to the cytocollagenous attachment^{87–89} (see Fig. 4-20). The integrins provide a mechanism for interaction of environmental stimuli and intracellular events.⁹⁰ In addition, the organised arrangement of the receptors on the cell surface and the proteins in the extracellular matrix provides a link for transducing production of sarcomeric force into development of ventricular pressure and ejection of blood.

DEVELOPMENT AND THE CYTOSKELETON

The organisation and numbers of myofibrils in the cardiac myocyte undergo prominent changes during embryonic and neonatal life. Early in development, the myofibrils appear to lack any particular orientation relative to other myofibrils, and do not appear to be connected. This lack of organisation is associated with a relatively low density of myofilaments. Before the content of myofibrils, expressed as a percentage of total volume of the myocyte, reaches that of the adult myocyte, the myofibrils become oriented parallel to the long axis of the myocyte.² Following the acquisition of this orientation, the myofibrils are linked as a thin subsarcolemmal shell surrounding a central mass of nucleus and mitochondria (see Fig. 4-5 and compare Fig. 4-22 with Fig. 4-23). In these immature cells, the large central mass of non-contractile material provided an internal load against which the myofibrils must contract. With further maturation, the myocyte achieves an ordered packing of alternating layers of myofibrils and mitochondria from one side of the myocyte to the other (see Fig. 4-5). All of these developmental changes are important in bringing about a more efficient transmission of development of force from the sarcomere.

The proteins that make up the cytoskeleton, and the sarcolemmal receptors for integrin, change with development, as does their distribution within the myocyte.^{86,88,89,91} The affinity of cardiac myocytes for specific components of the extracellular matrix also changes with development. These results are consistent with developmentally regulated expression of integrin receptor α -subunit isoforms. In the human, expression of desmin increases during fetal life, with the distribution of desmin into the integrated lattice within the myocyte being acquired by the end of the first year of life.⁹²

It is unclear how the developmental changes in the cytoskeleton contribute to the developmental increase in myocardial compliance (see Fig. 4-2). In isolated cardiac myocytes, the length of the sarcomeres in the neonatal myocyte is shorter than that of the adult myocyte, suggesting greater internal loads in the neonatal myocyte.² The perinatal

Figure 4-21 Segmental extension of titin filaments as the structural basis of passive tension-length relations of resting muscle. The titin filaments are illustrated as chains of filled circles along the top of the thick filaments and as coiled-coils extending from the end of the thick filament to the Z-disc (see also Fig. 4-16). The postulated structural events of the titin filaments that underlie the stress-strain curves are shown. The titin filament is represented as consisting of two mechanically distinct segments: an extensible segment in the I-band (*open symbols*) and an inextensible segment that is constrained by interaction with thick filaments (*solid symbols*). At slack sarcomere length (SL_0), titin may be flaccid, and stretching to SL_e causes a small increase in force. Beyond SL_e , a linear extension of titin segment generates an exponential increase in tension. At SL_y , the extensible segment becomes longer by recruiting previously inextensible titin resulting in the leveling of tension. The net contour length of the extensible segment of titin is longer in a sarcomere expressing a larger titin isoform, for example N2BA (see Fig. 4-16). (From Wang K, McCarter R, Wright J, et al: Regulation of skeletal muscle stiffness and elasticity by titin isoforms: A test of the segmental extension model of resting tension. *Proc Natl Acad Sci U S A* 1991;88:7101–7105, Figure 5.)

Figure 4-22 Longitudinal section of an isolated adult cardiac myocyte. T-tubule profiles are penetrating at the level of the Z-line of the cell surface, on the right, and appear as triads flanking each Z-line. Rows of mitochondria and myofibrils, which alternate across the image, typify the arrangement in the adult cell. The myofibril closest to the cell surface passes out of the section plane for a short distance, demonstrating that the mitochondria envelop each myofibril. A vesiculated gap junction is at the right (*arrowhead*). (From Nassar R, Reedy MC, Anderson PAW: Developmental changes in the ultrastructure and sarcomere shortening of the isolated rabbit ventricular myocyte. *Circ Res* 1987;61:465–483, Figure 7.)

switching in expression of isoforms of titin from longer highly extensible isoforms to shorter less extensible ones does not appear consistent with the developmental increase in myocardial compliance⁹³ (see Fig. 4-16). In that only a portion of the passive stiffness of the isolated myocyte is attributed to titin, developmental changes in the extracellular matrix, and switching of isoforms of the proteins within the extracellular matrix, may be a more important contributor to the developmental increase in passive compliance (see below).

DEVELOPMENT AND THE MITOCHONDRIA

Mitochondria undergo a developmental increase in crista thickness, number, size, and relative volume in the myocyte. These changes are most striking during early postnatal life.^{4,94–96} Their highly ordered relation to the myofibrils in the adult myocyte is acquired with maturation (compare Figs. 4-5, 4-22, and 4-23). The effects of ventricular workload on this postnatal process are suggested by the more rapid increase in mitochondrial number and size in neonatal left ventricular myocytes. Fetal mitochondria contain sparse and widely spaced cristae, or crests. Soon after birth, these crests become dense and closely packed. Although acquisition of other properties during development varies among species, the postnatal timing of these changes in mitochondria is common to all mammals. The developmental changes are consistent with the mitochondria having an increased importance in postnatal life as a source of energy for sarcomeric function, the maturational increase in the ability of the myocardium to utilize long-chain fatty acids, and myocardial metabolism becoming primarily oxidative, with long chain fatty acids being the primary substrate.

Figure 4-23 Longitudinal section of a myocyte isolated from the heart of a 3-week-old rabbit. Cell surface is to the left. A single myofibril lies just below the sarcolemma; mitochondria and a nucleus occupy the rest of the image. Note that in the immature cell, alternating rows of mitochondria and myofibrils are not present (compare Fig. 4-16). An incompletely vesiculated gap junction is seen at the arrowhead. (From Nassar R, Reedy MC, Anderson PAW: Developmental changes in the ultrastructure and sarcomere shortening of the isolated rabbit ventricular myocyte. *Circ Res* 1987;61:465–483, Figure 8.)

MYOCYTE-MYOCYTE CYTOSOLIC COMMUNICATION—GAP JUNCTIONS

Myocytes, although individual units anatomically, function as a syncytium. The cytosol of adjacent myocytes is coupled directly by gap junctions in the sarcolemma that are made up of connexons containing six identical units, connexins, which surround an aqueous pore.^{97,98} The channels in the sarcolemma of one cell join the channels in the adjacent cell. The intracellular communication is regulated by voltage, intracellular pH, calcium, and protein kinases.^{99–101} The channels in the gap junction are of sufficient size, at 1 to 2 nm in diameter, to fulfill a signalling role, permitting the diffusion of small molecules, up to 1 kDa in size, from one cardiac myocyte to another.^{11,102}

DEVELOPMENT AND MYOCYTE-MYOCYTE CYTOSOLIC COMMUNICATION

The density of gap junctions in the membranes increases during embryonic and fetal life in the mammal.^{103,104} Expression of isoforms of the connexins also changes with development.¹⁰⁵ With development, conductances across the gap junction increase, and sensitivity to transjunctional voltage decreases. The net result of these developmental increases in the density of the gap junctions and their conductance is better coupling between the myocytes in

adult myocardium, and a resultant increase in velocity of conduction.¹⁰⁶

EXTRACELLULAR MATRIX

The extracellular matrix is an important contributor to the passive and active mechanical properties of the myocardium. It has multiple components, including interstitial collagen types I and III, glycoproteins, such as fibronectin and laminin, and proteoglycans, such as heparan sulphate and hyaluronic acid.^{107,108} The interaction of this matrix with the cardiac myocytes requires the binding of the contained extracellular proteins to the receptors on the cell surface, the integrins.⁸⁶

The network that makes up the extracellular matrix is considered to have four levels: the epimysium, perimysium, endomysium, and basement membrane.¹⁰⁸ The basement membrane is considered to be a specialised outer layer of the sarcolemma, where collagen type IV, laminin, fibronectin, and heparan sulphate are found. The epimysium is characterised as the region of the subepicardium and subendocardium. Its firm attachment to the cells makes up the epicardium and endocardium. The perimysium of the heart consists of large cable-like bundles of collagen that connect the epimysial layer with the endomysium, and give the appearance of a coiled spring. The fibroblasts, the major producers of components of the extracellular matrix, and the two interstitial collagens, collagen I and collagen III, have contacts with the endomysial collagen, adjacent fibroblasts, and myocytes, and form a three-dimensional weave that is intimately associated with myocytes and the extracellular matrix.¹⁰⁹ The endomysial layer itself consists of connections between fibroblasts, connections between fibroblasts and myocytes, connections between myocytes, connections between the myocytes and the capillaries, and interactions between the cells and the extracellular matrix in the overall weave. The connections include bundles of collagen that connect the adjacent myocytes, as well as attaching the myocytes to the capillaries and other components of the extracellular matrix.

DEVELOPMENT AND THE EXTRACELLULAR MATRIX

The specialised outer layer of the sarcolemma, where laminin, fibronectin, and heparan sulphate are found, undergoes prominent changes during embryonic, fetal, and perinatal development. For example, laminin is localised to distinct patches of extracellular matrix associated with the sarcolemma during fetal development, is distributed extensively over the myocyte in the neonate, and in the adult heart is localised most heavily in the area of morphological specialisation, such as the integrin-containing sarcolemmal regions that are adjacent to the Z-discs.¹¹⁰ These interactions are involved in regulation of genetic expression, and myocytic differentiation.¹¹¹

The principal elements of the network of connective tissue in the fetus are the epimysium and the perimysium. The weave is poorly developed at birth.¹¹² The collagenous connections between the myocytes themselves, and with the capillaries, develop rapidly in the heart during the neonatal period. In late fetal development, collagen type I and III are present in very low amounts.¹¹² The acquisition

of the extracellular matrix during late fetal and early postnatal life with a relative increase in myocardial collagen may appear paradoxical when considered in the context of the developmental increase in myocardial compliance (see Fig. 4-2). A developmental change does occur, nonetheless, in the expression of the subtypes of collagen. Collagen type I provides rigidity, and type III provided elasticity. In the human, the ratio between these types is very high in the fetus, but falls with development.¹¹³ This differential expression of the two types may underlie the developmental increase in compliance. Developmental changes in the expression of other proteins within the extracellular matrix, and the subunits of integrin, may also contribute to the developmental increase in myocardial compliance (see Fig. 4-2). Importantly, the developmental increase in myocardial compliance will lead to enhanced ventricular diastolic function, and potentially improved systolic function.

DEVELOPMENT, SYMPATHETIC INNERVATION, AND THE ADRENORECEPTORS

The sympathetic nervous system is important in the process of growth and differentiation of cells, control of calcium, and modulation of the response of the contractile and membrane proteins to activation of membranes and calcium. The cardiac sympathetic nerves are derived from the neural crest.¹¹⁴ The response of the myocardium to β - and α -agonists precedes the acquisition of myocardial innervation.¹ The effects of exogenous catecholamines on myocardial function vary among species, and between investigations.^{1,115–118} Commonly, the myocardium becomes more responsive with maturation.^{1,117} The intramyocardial availability of noradrenaline, which stimulates both α - and β -adrenoreceptors, increases with the developmental acquisition of the intramyocardial adrenergic plexuses, and the associated increased storage of the neurotransmitter in their synaptic vesicles. This developmental increase in myocardial stores of noradrenaline is reflected in the human by an increased ability of the myocardium to take up noradrenaline during gestation.¹¹⁹ The maturational time course of cardiac innervation varies among species. In some, innervation appears during fetal life while, in others, innervation is acquired during postnatal life.^{1,120–122} In the human fetus, nerves grow into the heart along the large coronary arteries before extending into the myocardium. The developmental acquisition of sympathetic innervation provides an intrinsic system within the myocardium to enhance contractility and increase heart rate.

The functional consequences of these maturational changes are multiple. The coupling of receptors to the adenylate cyclase system is acquired with maturation, resulting in more effective phosphorylation of target proteins following adrenoreceptor stimulation. Phosphorylation of the α_1 -subunit of the L-type calcium channel dependent on protein kinase, itself dependent on cyclic adenosine triphosphate, results in an increase in calcium current. Removal of phospholamban inhibition of SERCA, by way of phosphorylation of protein kinase A, results in an increase in activity of SERCA, a more rapid uptake of cytosolic calcium by the sarcoplasmic reticulum, and a greater

intracellular store of calcium for release during subsequent contractions. The combination of these effects on the calcium channel and the sarcoplasmic reticulum is an increase in the peak of the calcium transient, and more rapid fall of calcium itself to diastolic levels. Phosphorylation of troponin I dependent on cyclic adenosine triphosphate results in decreased sensitivity of the myofilaments to calcium, allowing the cardiac contraction to relax more rapidly, the so-called lusotropic effect, and, in addition, a blunting of the Frank-Starling relation. These, and other examples, characterise the complex interactions that result from the developmental changes in the autonomic nervous system and the systems intrinsic to the regulation of calcium and sarcomeric function.

The functional consequences of the developmental changes in the expression of the cardiac troponin T isoforms are considered in the context of the cytosolic calcium transient in myocytes from the immature and the adult rabbit heart. The higher calcium sensitivity of troponin-calcium binding and force development conferred by the longest and most acidic of the cardiac troponin T isoforms suggest that the higher expression of these isoforms in the neonatal myocyte may partially compensate for the lower systolic calcium transient in the immature myocyte.
- Altamirano J, Li Y, DeSantiago J, et al: The inotropic effect of cardioactive glycosides in ventricular myocytes requires Na⁺-Ca²⁺ exchanger function. *J Physiol* 2006;575:845–854.
The demonstration that sodium-calcium exchanger function is required for the inotropic effect of cardiac glycosides in ventricular myocytes is consistent with the positive effect of cardiac glycosides on myocardial contractility in the immature heart where exchanger expression may be higher.

- Gordon AM, Homsher E, Reginier M: Regulation of contraction in striated muscle. *Physiol Rev* 2000;80:853–924.

The regulation by calcium of contraction in cardiac muscle is exerted primarily through effects on the thin filament. The three-state model of thin filament activation and the structural and biochemical studies that underlie this model are reviewed.

- Day SM, Westfall MV, Fomicheva E, et al: Histidine button engineered into cardiac troponin protects the ischemic and failing heart. *Nat Med* 2006;12:181–189.

The molecular basis for the differential effect of acidic pH on the function of myofilaments containing cardiac troponin I and slow skeletal muscle troponin I is revealed. A single histidine residue difference between the two isoforms results in acidic pH having a greater negative effect on myofilaments containing cardiac troponin I. This difference is of fundamental importance in the developing heart, where ss is the dominantly expressed isoform during fetal and perinatal life.

- Gomes AV, Venkatraman G, Davis JP, et al: Cardiac troponin T isoforms affect the Ca^{2+} sensitivity of force development in the presence of slow skeletal troponin I: Insights into the role of troponin T isoforms in the fetal heart. *J Biol Chem* 2004;279:49579–49587.

The developmental changes in the cardiac troponin T isoforms have been shown to confer onto myofilaments in the developing heart a greater sensitivity to calcium. Here, the slow skeletal muscle and cardiac forms are shown to modulate the effects of the cardiac isoforms. The contemporaneous expression of the slow skeletal muscle form in the developing heart amplifies the positive effects of the fetal cardiac isoforms.

Physiology of the Developing Heart

HELENA M. GARDINER

The heart is the first organ to become fully functional in the developing embryo, providing the circulatory system necessary for embryogenesis and subsequent fetal development when growth can no longer be sustained by diffusion of nutrients from the surrounding tissue. The rapid advances in genetics and molecular biology have revolutionised our knowledge of the developing embryonic heart. In similar fashion, technical improvements in imaging and non-invasive physiological recording of the early human fetus have enabled us to study the human heart non-invasively from the first trimester, and build on information from studies of the chick embryo model.¹

The drive towards a greater understanding of the molecular aspects of cardiac development during the previous decade temporarily pushed the physiologist to the sidelines in cardiovascular research.² The pendulum is now swinging back to a combined approach that will allow translation of information obtained from basic science into clinical practice, and provide a unique picture of human cardiovascular development along with the long-term cardiovascular responses to intra-uterine and postnatal challenges. In this chapter, I review our current understanding of the physiology and pathophysiology of the human heart in fetal life, and determinants of a successful transition in the perinatal period.

EMBRYONIC CIRCULATION

In the chick embryo, rhythmic pulsations of approximately 50 Hz begin in the ventricle, coincident with fusion of cushions in the ventriculo-arterial segment. These pulsations, although rhythmic, are insufficiently forceful to set blood in motion, or to generate recordable pressures, the onset of electrical activity preceding myofibrillogenesis.³ The elaboration of intracellular contractile proteins is incomplete at this stage, the functional contractile units are not fully assembled, and the matrix of collagen has not yet formed.⁴ Once cardiac rhythm is established, nonetheless, the myofibrils within the myocytes become aligned and, as the heart rate rises, the direction of flow of blood is established to provide a circulation for the growing embryo. Growth of the atriums and ventricles is associated with an increase in the rate of pulsation of the primitive heart tube. This establishes the direction of propagation of the peristaltic waves of contraction from atrium to ventricle.

Cardiac myocytes isolated from the venous sinus, atrium, and ventricle at this developmental stage in the chick embryo all exhibit automaticity with different intrinsic rates of contraction. The ventricle is slowest, at approximately 50 to 60 Hz, while cells from the venous

sinus have the fastest rate, with the atrium being intermediate. The earliest recordings of human fetal cardiac activity have been obtained at 25 days after fertilisation by high-frequency trans-vaginal ultrasound. At this stage, only the amniotic sac is visible, and no embryonic poles are identifiable. The mean heart rate at this stage of gestation is approximately 90 beats per minute and regular. This most likely represents atrial rhythm. The mechanism responsible for the characteristic early increase in heart rate between the fifth and eighth weeks of gestation is uncertain. The initial rapid increase in the frequency of contraction is comparable to that occurring in the chick embryo. It is associated with the transition of the pacemaker, first from ventricle to atrium as fusion occurs between the two, and then to the venous sinus as this segment becomes incorporated into the right atrium. The precursor of the sinus node, which assumes the role of the cardiac pacemaker subsequently, is formed at the junction of the developing superior caval vein with the atrium.

By 8 to 10 weeks, the mean heart rate in the human fetus varies between 160 and 170 beats per minute, declining to an average of 150 beats per minute at 15 weeks. After this, the rate declines progressively towards term. This pattern of change in heart rate, seen during embryonic and fetal life in the human, parallels that occurring in the chick, in which cardiac action begins between 33 and 36 hours at a rate of 60 beats per minute, and increases to 220 beats per minute by the eighth day of gestation.

In the human, there is little variation of the mean heart rate at any particular gestational age up until 15 weeks, as the pre-innervated immature cardiovascular system does not rely on heart rate acutely to control cardiac output. The maximum cardiac output occurs at the intrinsic heart rate at each embryonic stage, suggesting that, as in the chick, cardiac function is optimised by the systolic and diastolic time intervals.⁵

Alterations in heart rate significantly affect cardiac performance,⁶ and there is no compensatory change in cycle length in response to preload as is seen in the more mature heart. Human embryos die if their heart rate falls, or if they experience tachycardia.⁷ This indicates that, during cardiogenesis, extremes of heart rate are not commensurate with long-term viability.⁸

AUTONOMIC CONTROL

The subsequent decline in heart rate after 10 weeks, and the increased variability in heart rate after 15 weeks of gestation, may be explained by a combination of maturational

changes. These include development of the nervous control of the heart, stresses associated with cardiogenesis, and changes in the handling of calcium by the myocyte.

Innervation of the mammalian heart is similar to that in the chick heart, consisting of parasympathetic, sympathetic, and sensory components, all of which derive from the neural crest.⁹ Although parasympathetic and sympathetic innervation of the heart occurs early during cardiac development, the time period between innervation, neuroeffector transmission, and functional neurotransmitter reactivity of both cholinergic and adrenergic receptors, varies greatly between species. Functional adrenergic and muscarinic cholinergic receptors have been detected in the heart of very early chick embryos.¹⁰ These differences in the timing to achieve a balance between parasympathetic and sympathetic reflex neuroeffector transmission in varying mammalian species relates largely to the maturity and independence of the individual animal species at birth. The variability in heart rate reflects the changing status of the autonomic nervous system as the heart becomes more sensitive in response to internal and external stimuli. Spectral analysis of the variability of heart rate in the normal human fetus demonstrates gestational-related changes ascribed to the imbalance between sympathetic and parasympathetic neuroactivity consistent with cardiovascular maturity of the fetus. Maturation of autonomic control has been difficult to assess in the human fetus until relatively recently, as the cardiocotograph has been the only non-invasive tool available to measure the variability in heart rate. This system provides limited information, as it uses a mean of three fetal heartbeats, compared with beat-to-beat recordings of cardiac activity. Furthermore, it does not produce an electrical signature. New tools, such as magnetocardiography, have permitted a more detailed assessment of the developing electrophysiology in the human fetus, and will be discussed later in this chapter.

THE BIOPHYSICAL PROPERTIES OF FETAL MYOCARDIUM

The biophysical characteristics of fetal, neonatal and adult myocardium have been investigated in a number of mammalian species, but the studies in the sheep and rabbit have provided the majority of information.^{11,12} (See also Chapter 4.) These studies have consistently demonstrated that active development of tension is lower in fetal than adult myocardium at all lengths, including the optimal length.¹¹ In addition, in the ovine fetus, resting tension was greater than that in the adult animal; consequently, operational development of peak tension was less at all lengths (Fig. 5-1). The velocity and extent of shortening in fetal myocardium were lower than in adult myocardium at every level of developed tension (Fig. 5-2). Explanations for this have been sought. Sarcomeral length is optimal, and not significantly different, in fetal and adult myocardium. The difference in developed tension, therefore, cannot be accounted for entirely by the greater proportion of non-contractile protein per unit cross sectional area of fetal myocardium. It may be explained in part by the different sensitivity of the fetal contractile proteins troponin and myosin to cytosolic calcium.¹²

Figure 5-1 Comparison of peak isometric passive and active length-tension curves in the fetal heart and adult heart. The former had consistently higher resting tension over the range of muscle lengths. (Reproduced with permission from Friedman WF: The intrinsic physiologic properties of the developing heart. *Prog Cardiovasc Dis* 1972;15:87-111.)

In the early human fetus, handling of calcium depends on diffusional gradients through the sarcolemma in the absence of a developed sarcoplasmic reticulum. Sarcoplasmic calcium ATPase is expressed in a downstream gradient along the primitive heart tube, resulting in increased contraction duration in the outlet portions of the heart. By the 38th day of gestation, the early human myocardium may be divided into primary and working functional components. The primary components are characterised by slow conduction of the cardiac impulse, owing to the low density of gap junctions and the presence of slow voltage-gated calcium ion channels. The working components, found in the atriums and ventricles, permit fast conduction through the development of gap junctions and of fast voltage-gated sodium channels. The sarcoplasmic reticulum later regulates calcium release in the cell and is known to play an important role in the frequency-dependent facilitation of the L-type calcium current in the rat ventricular myocyte.¹³

The three major connexins, 40, 43, and 45, are present in cardiac myocytes and are developmentally regulated. Immunofluorescence microscopy has been used to compare the distribution of these within the developing mouse and human heart. In the human, connexin 45 is most prominent in the conduction tissues; connexin 40 is also abundant in conduction tissues, particularly in the Purkinje fibres, and in the atrial rather than in the ventricular muscle; and connexin 43 is distributed in the ventricular myocardium, and plays an important role in conduction across gap junctions.¹⁴ Downregulation of gap junctional conduction has been demonstrated in cardiomyopathy caused by tyrosine phosphorylation of connexin 43.¹⁵ Altered patterns of calcium ionic fluxes, and of abnormal β -adrenoreceptor stimulation in diseased adult myocardium,¹⁶ may also occur in the developing heart exposed to chronic hypoxaemia associated

Figure 5-2 Relationships between extent (A) and velocity (B) of the shortening and developed tension in the fetal and adult sheep. These plots demonstrate a lesser degree of shortening and a lower velocity of shortening in the fetal compared with the adult sheep. with restriction of growth, or in conditions with abnormal volume loading.

PROTEIN COMPONENTS

Troponin

The differences between fetal and adult myocardial contractile function are, in large part, related to their regulatory and structural protein components. Different isoforms of troponin and myosin heavy chain have been identified in fetal and adult myocardium from a number of mammalian species, including humans. These are genetically programmed during early embryonic development, and are modulated by specific neurohormones. Troponin T has been studied extensively and cloned. It regulates contraction in response to the concentration of ionic calcium.¹⁷ Multiple isoforms have been recognised, the gene *TNNT2* being identified on chromosome 1q23. Slow skeletal muscle troponin T is the predominant isoform throughout fetal life, but this is lost after birth. Only troponin I is detectable by 9 months of postnatal life.¹⁸ The genes coding for these two isoforms lie in close apposition, but show independent tissue-specific expression, although this close arrangement may complicate investigation of mutations implicated in cardiomyopathy.¹⁹ A knock-out model of myocardial troponin I has shown that, while affected mice are born healthy, they begin to develop heart failure by 15 days. They have an isoform of troponin I that is identical to slow skeletal troponin I, and permits survival, but this isoform disappears after birth despite the lack of compensatory myocardial troponin I. Cardiac muscle is abnormal in the absence of troponin I. The ventricular myocytes have shortened sarcomeres, and elevated resting tension under relaxing conditions, and they show reduced sensitivity of their myofilaments to calcium under activating conditions.²⁰ Calcium is released more readily in fetal isoforms of *SSTN1* than adult muscle cardiac troponin T isoforms. In its presence, troponin T shows increased calcium sensitivity of force development.²¹ In contrast, a reduction in calcium sensitivity of force development is seen in individuals with dilated cardiomyopathy caused

by mutation of troponin T1 in the R141W and delta K210 regions.²²

Beta-myosin

The β -myosin heavy chain isoform predominates in all fetal mammals thus far examined, including humans. This isoform is more efficacious in the fetus, conferring biochemical and mechanical advantages on fetal myocardium, in that the β -isoform utilises less oxygen and ATP than the adult α -isoform in generating the same amount of force. Recent investigations have shown re-expression of fetal genes that downregulate adult, but not fetal, isoforms in response to increased cardiac work and subsequent mechanical unloading. This response appears to result in mechanical improvement, and may be important in future strategies for the management of cardiac failure.²³

The myosin heavy chain carries the ATPase site. The enzymic kinetics of the ATPase are specific for each isoform. This has importance, because it is the rate at which ATPase hydrolyses ATP that primarily determines the force-velocity relationship during myocardial contraction. This explains the fundamental differences in active and passive mechanics between fetal and adult myocardium.²⁴ The transition from fetal to adult isoforms of myosin heavy chain around birth is similar to the controlled switch from fetal to adult haemoglobin, and represents stage-specific regulation of genetic expression of the proteins prior to birth. While a number of hormones, and particularly thyroid hormone,^{25,26} are known to modulate the phenotypic expression of the myosin heavy chain, the factors responsible for the precise timing of the transition from fetal to adult isoforms remain unknown.

Chronic Heart Failure

Chronic heart failure in the human adult is characterised by left ventricular remodelling and reactivation of a fetal gene programme, with alterations of expression of micro RNA closely mimicking those observed in fetal cardiac tissue.²⁷ Furthermore, transfection of cardiomyocytes with a set of fetal micro RNAs induced cellular hypertrophy, as

well as changes in gene expression comparable to that seen in the failing heart. Re-expression of fetal genes may also be seen in mice having obstruction to the left ventricular outflow tract. The myocardium achieves stable mural stress by hypertrophic response in the presence of pressure overload. Once compensated cardiac hypertrophy had occurred in these experiments, most of the genes returned to basal levels of expression. Thus, it appears that pressure overload results in transient early changes in genetic expression, and this may reflect a beneficial response, as there is no evidence of deterioration of haemodynamic function or heart failure.²⁸ This response, nonetheless, may result in a decompensated hypertrophic phenotype. There is some evidence in the Wistar rat model that hearts responding in a decompensated form show activation of pro-apoptotic pathways, in contrast to those showing compensated hypertrophy, who appear to block this using p38-MAPK. In these experiments, the response occurred early after the induction of the phenotype, and thus might be one helpful early predictor of clinical outcome, potentially allowing early interventional therapy.²⁹

CIRCULATORY PHYSIOLOGY IN THE NORMAL HUMAN FETUS

The Fetoplacental Circulation

Knowledge of the physiological changes in the circulatory system beyond the period of cardiogenesis and embryonic life, including growth of the cardiac chambers, haemodynamics and oxygen saturation of the fetal pathways, ventricular interaction, and distribution of the cardiac output, are largely based on studies of the ovine fetus.^{30–32} These experimental investigations have provided important insights into ovine fetal circulatory dynamics, which are similar to those in the human fetus, even though there are quantitative differences in the distribution of flows of blood, especially to the brachiocephalic and uteroplacental circulations in the human fetus, that caution against unconditional extrapolation.

The fetal circulation is characterised by four shunts. These are, first, within the placenta, second, across the venous duct, which connects the intrahepatic portion of the umbilical vein to the inferior caval vein, third, through the oval foramen, which is essential for filling of the fetal left ventricle, and fourth, across the arterial duct, which directs the majority of flow through the right ventricular outflow tract into the descending aorta below the level of the isthmus in the structurally normal heart. The patterns of flow through all these structures have been studied non-invasively in health and disease states using echo Doppler.

The Placenta

The placenta plays a major role in the fetal circulation, fulfilling the functions of the lung for exchange of gases, and for the kidney and gastrointestinal tract in delivery of nutrients and excretion of metabolites. The fetal side of the placenta, which develops from the chorion, receives blood from paired umbilical arteries, which take origin from the internal iliac arteries of the fetus. The umbilical arteries within the cord spiral around the umbilical vein, and then divide into branches at the junction of the cord

and the placenta. These branches have a radial disposition. The terminal branches perforate the chorionic plate, and form anastomotic plexuses within the main stem of each chorionic villus. Each main stem possesses a derivative of the umbilical artery, which penetrates the thickness of the placenta, dividing to form a huge network of capillary plexuses. These project into the inter-villous spaces that contain maternal blood.³² As a result, there is a very extensive surface area within each chorionic villus, across which exchange of gas occurs down gradients for both oxygen and carbon dioxide. There is, essentially, no mixing of maternal and fetal blood. Following oxygenation within the chorionic villi, the blood enters the venous radicals within each main stem. These efferent venules become confluent at the junction of the placenta and umbilical cord to form the umbilical vein.

The Venous Duct

The umbilical vein carries oxygenated blood, with an oxygen saturation of between 80% and 90%, from the placenta to the umbilical cord (Fig. 5-3). The cord enters the fetal abdomen, where it divides to form the portal sinus and the venous duct. The portal sinus joins the portal vein, while the venous duct carries oxygenated blood to the inferior caval vein. The origin and proximal part of the venous duct act as a physiological sphincter, which, during hypoxaemia

Figure 5-3 A simplified scheme of the fetal circulation. The shading indicates the oxygen saturation of the blood, and the arrows show the course of the fetal circulation. Three shunts permit most of the blood to bypass the liver and the lungs: the venous duct, the oval foramen, and the arterial duct. (Adapted with permission from Moore KL: *The cardiovascular system*. In *The Developing Human: Clinically Oriented Embryology*, 5th ed. Philadelphia: WB Saunders, 1993.)

Figure 5-4 Parasagittal view of the fetal liver and heart. Colour flow mapping illustrates flow in the venous duct slipstreaming within the inferior caval vein, through the oval foramen to enter the left atrium.

or haemorrhage, results in an increased proportion of oxygenated blood passing through the duct to the inferior caval vein and to the heart, with less exiting to the portal sinus and the liver.³³ The oxygenated blood from the venous duct can be demonstrated coursing along the medial portion of the inferior caval vein after their confluence. Flow in the inferior caval vein continues towards the head into the inferior aspect of the right atrium, where a proportion of the oxygenated blood is slipstreamed by the lower border of the infolded atrial roof, also known as the dividing crest or crista dividens. This structure, therefore, acts as a baffle diverting blood into the atrium, a process which can readily be visualised during echocardiography (Fig. 5-4).

A proportion of the oxygenated blood is diverted to the heart, and this proportion varies in different mammalian species. The remainder of the mainly desaturated blood mixes with the desaturated blood from the mesenteric, renal, iliac, and right hepatic veins, and with that from the coronary sinus and the brachiocephalic veins.

The Oval Foramen

Patency of the oval foramen is essential to enable filling of the left side of the heart in the fetus, as pulmonary venous return is low. The proportion of oxygenated blood returning to the heart via the inferior caval vein that crosses the oval foramen to reach the left side of the heart also varies between species. This oxygenated blood mixes with the desaturated blood returning to the left atrium via pulmonary veins such that, after complete mixing in the left ventricle, the oxygen saturation is approximately 60%, compared with levels between 50% and 55% in the right ventricle. Blood from the left ventricle is directed to the brachiocephalic circulation, thus supplying the most oxygenated blood to the brain, which grows at a disproportionately greater rate in the human fetus compared with the rest of the body. The majority of blood ejected into the ascending aorta by the left ventricle is directed cephalad to the head and upper limbs, and only about one-third of the left ventricular stroke volume crosses the aortic isthmus to reach the descending thoracic aorta and lower body.

Although the arterial saturation of oxygen is comparatively low, extraction of oxygen by the tissues is facilitated by the leftward displacement of the dissociation curve for oxygen of fetal haemoglobin compared with that of the adult.

The Arterial Duct

The mixed venous return has an oxygen saturation of approximately 40%. This blood passes through the tricuspid valve into the right ventricle, where mixing occurs before it enters the pulmonary trunk, where the oxygen saturation is between 50% and 55%. The majority of blood in the pulmonary trunk passes through the arterial duct to the descending thoracic aorta, with only a small proportion continuing to the lungs via the right and left pulmonary arteries. The arterial duct enters the descending aorta immediately distal to the origin of the left subclavian artery, and blood is directed to the descending thoracic aorta by the geometry of its insertion, and also by a shelf-like projection at its upper insertion. The degree of patency of the arterial duct is regulated by the periductal smooth muscle cells, which produce prostaglandins. In the human fetus, ductal flow may be compromised by maternal ingestion of inhibitors of prostaglandins, such as the non-steroidal anti-inflammatory agents. Blood from the arterial duct mixes with that crossing the aortic isthmus from the aorta. This produces a saturation of oxygen between 50% and 55% in the descending aorta, from which a major proportion returns to the placenta via the umbilical arteries for reoxygenation.

FETAL DEVELOPMENTAL PHYSIOLOGY

Cardiac Growth

The first systematic study of cardiac growth in the human fetus was made using a large series of normal hearts obtained at postmortem. This established the relationship between total body weight, total heart weight, and the variability of heart weight with gestational age.³⁴ Detailed examination of the heart is now possible during the first trimester using trans-vaginal and transabdominal ultrasound.^{35,36} These scans can provide excellent imaging of the fetal heart from 12 gestational weeks, even in multiple pregnancies. Diagnostic views at normal obstetric scanning depths can be obtained using modern ultrasound transducers with limits of resolution of about 50 μm in the axial plane at 6 MHz, and less than 100 μm in the lateral plane. As a result, morphological and physiological data have become easier to record and more reliable. Z-scores have been derived to take account of the effects of fetal gestation and growth on the size of vessels, valves and chambers. These are particularly useful for quantitative comparison when cardiac structures are very hypoplastic.^{37,38} They are downloadable from references 37 and 38. Models derived from anatomical specimens have been superseded by three- and four-dimensional technology, which now permits assessment of volumes and morphology non-invasively in larger cohorts.^{39,40} Magnetic resonance imaging, however, is still not sufficiently robust to provide cardiac imaging of comparable quality to ultrasound in the fetal heart.

Assessment of the Fetal Circulation

The fetal circulation is assessed using pulsed wave Doppler. Initial studies used blind continuous wave ultrasound of the umbilical cord. Technical improvements, including newer colour Doppler modalities such as energy and directional power, have enabled the visualisation and interrogation of smaller vessels in regional circulations and indicators of fetal wellbeing have been derived.^{41,42}

In the healthy placenta, the copious villous bed allows exchange of oxygen and metabolic products. When placental function is severely reduced, as in fetuses with restricted growth, increased placental resistance leads to a reduction in total delivery of arterial oxygen to the fetus because of the reduction in mean placental return, even though the content of oxygen of the umbilical venous blood is often near normal. The fetal brain, heart and adrenal glands respond to this pathological state by drawing increased flow, thus requiring an increase in combined ventricular output to provide it. In the human fetus, the brain is the largest organ, and the healthy, responsive fetus is able to reduce cerebral resistance by arteriolar dilation.

The pulsatility index was derived in the 1970s to quantify waveforms in the umbilical cord, and assess fetal compromise. It uses the ratio of flow velocities as shown in Figure 5-5. Abnormalities of flow in the cord are characterised firstly by a reduction, and then a reversal, of diastolic velocities, thus increasing the pulsatility index. This may be accompanied by abnormalities of the umbilical vein as seen in Figure 5-6.

Initial experimental work in the fetal sheep model demonstrated a redistribution of flow in response to hypoxaemia.⁴³ With the availability of non-invasive Doppler techniques, the observed low diastolic flow was associated with uteroplacental insufficiency.⁴⁴ On the fetal side of the placenta, an increased resistance to flow in growth-restricted pregnancies was described.⁴⁵ Evidence of redistribution of flow in the growth-restricted human fetus during the same period was provided by a comparison of Doppler waveforms in the carotid, aortic and umbilical arteries, and also in the middle cerebral artery.⁴⁶⁻⁴⁸ Animal work has supported the concept that, in the presence of uteroplacental

Figure 5-5 Diagram illustrating the pulsatility index calculated from the ratio of (maximum velocity – minimum velocity)/mean velocity. (With permission from Gosling RG, King DH: Ultrasonic angiology. In Marcus AW, Adamson L [eds]: Arteries and Veins. Edinburgh: Churchill Livingstone, 1975, p 71.)

Figure 5-6 Doppler (A) of normal flow in the umbilical artery (UA) and vein (UV) showing prograde flow in diastole and absence of venous pulsation. **B**, Absence of end diastolic flow in the umbilical artery (AEDF) increases the pulsatility index in the umbilical artery of pregnancies suffering from placental dysfunction. The Doppler trace also shows abnormal venous pulsations associated with fetal hypoxaemia or increased systemic venous pressure. **C**, Reversed end-diastolic flow (REDF) in the umbilical artery signifying increasing placental resistance.

insufficiency, the cerebral circulation becomes the vascular bed with the lowest impedance in the fetoplacental circulation. As systemic impedance rises, flow is directed in a retrograde manner about the arch towards the cerebral circulation.⁴⁹ Increased flow to the brain results in a decreased pulsatility index recorded usually in the middle cerebral artery. Auto-regulatory arterioles are sensitive to the local concentration of metabolic products, but will not function if the surrounding tissue is metabolically inactive. This may misleadingly manifest as a normalisation of cerebral Doppler flow waveforms in terminally sick fetuses just prior to their intra-uterine death.⁵⁰

Arterial and venous Doppler waveforms have become incorporated as standard measurements in surveillance of the high-risk pregnancy,⁵¹ with the latter shown to provide a more specific predictor of fetal compromise.⁵² Of the Doppler measurements used in evaluation, absence or reversal of end-diastolic flow in the descending aorta or umbilical artery of the fetus is seen first, and may be tolerated for a period of weeks in the compromised growth-restricted fetus, but once changes are seen in the systemic veins, imminent delivery is required.⁵³

Flow in the Venous Duct

The venous duct has been investigated at length because it occupies a unique physiological position as a regulator of oxygen in the fetoplacental circulation. Animal studies first demonstrated streaming of oxygenated blood from the umbilical vein through the oval foramen into the left side of the heart, estimated at half of the returning flow. The degree of shunting in the human fetus is less, being estimated at between one-quarter and two-fifths.³³ The determinants of shunting include the differing resistances of the portal vasculature and venous duct, along with other influences such as blood viscosity, umbilical venous pressure, and mechanisms

Figure 5-7 Abnormal Doppler flow in the venous duct showing reversal of flow coincident with the wave of atrial contraction.

of neural and endocrine control. The waveforms measured within the venous duct have been found to remain normal for long periods during placental compromise, reflecting its essential role in the fetal circulation.⁵⁴ Patterns in the umbilical vein also act as a barometer of fetal wellbeing. These are caused by the dilation of the venous duct in response to fetal hypoxaemia that reduces impedance, and allows pressure waves to travel in a retrograde fashion from the right atrium to the umbilical vein resulting in venous pulsations. Absent or reversal of flow in the venous duct is usually an ominous sign (Fig. 5-7). It reflects fetal hypoxaemia, and may result in emergency delivery by caesarean section. An alternative explanation for absent or reversed end-diastolic flow in the venous duct is increased central venous pressure, seen particularly where there is obstruction within the right heart, such as pulmonary atresia with severe tricuspid regurgitation (Fig. 5-8). This may also result in fetal hydrops and intra-uterine death.^{55–57}

A combination of Doppler parameters and assessment of fetal myocardial function has been combined to create a cardiovascular profile.⁵⁸ This scoring system includes the size of the heart and venous Doppler parameters. The best predictor of adverse outcome remains abnormal venous Doppler, and may be predictive when used in isolation.^{52,53}

Flow Across the Aortic Isthmus

Only approximately one-third of left ventricular output, or one-tenth of total cardiac output, flows through the aortic isthmus. One consequence of this is that the isthmal diameter is less than that of the transverse arch, and shows a characteristic Doppler pattern (Fig. 5-9). Experimental increases in systemic impedance in the lamb, mimicking placental insufficiency in the human, have been shown to reduce or stop isthmal flow.⁴⁹ In the human, where flow to the brain is 8 to 10 times that of the lamb, the hypoxic-mediated increase allows a reduction in cerebral impedance, with reversal of flow about the aortic arch that can be demonstrated on pulsed wave Doppler.⁵⁹

In fetuses with intra-uterine restriction of growth, abnormal arterial and venous Doppler findings influence perinatal outcome. At delivery, brain sparing was associated with hypoxaemia and abnormal venous flows with acidaemia. Abnormal flow in the venous duct predicts fetal death.^{51–53}

Figure 5-8 Colour flow mapping (A) of a fetal tricuspid regurgitant jet and Doppler velocity (B) measuring 1.84 m/sec and of moderate duration with sufficient time for ventricular filling. There is severe tricuspid regurgitation (C) at 4.37 m/sec of long duration.

Growth restricted fetuses with abnormal venous flow have worse perinatal outcome compared to those where the abnormality in flow is confined to the umbilical or middle cerebral arteries. In fetuses with low middle cerebral arterial

Figure 5-9 The fetal aortic arch (A) showing the origins of the brachiocephalic (BCA), left common carotid (LCC), and left subclavian (LSCA) arteries. Doppler of flow in the aortic isthmus (B) shows superimposed waveforms of earlier aortic flow and the later flow through the ductal arch.

pulsatility, an abnormal venous Doppler signal indicates further deterioration.⁶⁰

A combination of Doppler indexes shown to be predictive of the optimal time for delivery of the sick fetus has been studied to identify whether they are predictive of early cerebral injury if combined with imaging techniques.⁶¹ Abnormal fetoplacental flow did not appear to correlate with cerebral injury, but evidence of cerebral redistribution, as measured by the ratio of the pulsatility indexes of the umbilical artery compared to the middle cerebral artery, was associated with reduced total volume of the brain. The significance of this in neurodevelopmental outcome remains uncertain, and requires further investigation.

Flow of Blood to the Lungs

The flow of blood in the lungs of the normal human fetus has been calculated non-invasively from the difference in estimated volumes in the arterial duct and in the pulmonary trunk using Doppler ultrasound. In this way, an increase with age for pulmonary flow from 13% to 25% has been described in a cross-section of normal fetuses studied from 20 to 30 weeks of gestation, and an increase in the proportion of the cardiac output from the right side to 60% at term.⁶² Pulmonary vascular resistance increases during the last trimester. This again changes the balance of the cardiac output, increasing flow into the systemic circulation.

It is clinically helpful to predict infants with important fetal pulmonary hypoplasia, both to aid counselling of parents, and to prepare the resources required for neonatal resuscitation and support. Doppler parameters such as the pulsatility index have not proven to be discriminatory for pulmonary hypoplasia, for which there is currently no good antenatal test.⁶³ Early echocardiographic ratios, such as the ratio of sizes of the lungs and head, were derived to predict pulmonary hypoplasia in cases with diaphragmatic hernia. A ratio below 0.6 has been associated with poor outcome, whereas one above 1.4 has been associated with survival.⁶⁴ Alternative indexes of the ratio of fetal lung volume to fetal body weight using magnetic resonance imaging in combination with ultrasonography have been

devised.⁶⁵ Others have used magnetic resonance imaging alone to assess the total lung volume by comparing the signal intensity of lung to that of spinal fluid.⁶⁶ These may prove to be more promising methods for predicting fetal pulmonary hypoplasia than Doppler indexes alone.

Coronary Arterial Flow

In normal fetuses, flow in the coronary arteries is not usually seen until the third trimester. Reference ranges for velocities have been described, and do not appear to change with gestational age in the structurally normal heart.⁶⁷ Visible flow was first described in terminally sick fetuses, and proposed as an additional predictor of adverse outcome⁶⁸ (Fig. 5-10). Animal studies of myocardial flow show that coronary reserve is mediated by nitric oxide and, therefore, changes during hypoxaemia.⁶⁹ This finding has been termed fetal cardiac sparing.⁷⁰ Accordingly, visible flow in

Figure 5-10 Colour flow mapping demonstrating visible coronary flow in the right coronary artery (RCA).

the coronary arteries is attributed to an increased volume of flow secondary to low fetal arterial content of oxygen.

Fetal ultrasound may demonstrate visible coronary arterial flow in conditions associated with restriction of growth, anaemia, constriction of the arterial duct, and bradycardia, thus demonstrating short-term auto-regulation and long-term alterations in myocardial flow reserve in the human fetus. It can be demonstrated in growth-restricted fetuses earlier in gestation than in appropriately grown fetuses and at higher velocity. Fetuses with anaemia show the highest velocities in the coronary arteries, perhaps reflecting increased left ventricular output due to a reduction in cerebral impedance in response to both pathological situations. Coronary arterial flow is no longer visible once the underlying cause has been treated, for example by intra-uterine fetal transfusion for anaemia, or by stopping any causative medication such as indomethacin in the case of constriction of the arterial duct. Visualisation of flow coincides with important increases in the Doppler velocity Z-scores in the umbilical artery, inferior caval veins, and venous duct. The greatest change was observed in the venous duct Z-score occurring 24 hours before visible coronary arterial flow was identified. These changes were associated with adverse perinatal outcomes.⁷¹

It is relatively easy to demonstrate abnormal vascular connection between the coronary arteries and ventricular cavities, particularly in association with obstructed outflow tracts. Postnatal coronary arterial steal may be predicted by reversal of flow in the aortic arch, and coronary stenoses or occlusion by the finding of retrograde flow at high velocity (Fig. 5-11). These findings are important to discuss during antenatal counselling, as outcomes for these babies may be poor, and associated with postnatal death.

Intracardiac Flows

In the early embryo, gradients across the atrioventricular orifices act as a resistance to, and regulate, the flow of blood, thus influencing ventricular development.⁷² As the ventricular mass becomes trabeculated, so its mass increases while stiffness decreases, thus optimizing ventricular filling and ejection. Increasing cardiac efficiency is associated with increasing myocardial mass and competence of the atrioventricular and arterial valves.⁷³ Trans-vaginal

Doppler ultrasound of the human fetal heart has confirmed that ventricular inflow waveforms are monophasic before 9 weeks of gestation, becoming biphasic by 10 weeks. Atrio-ventricular valvar regurgitation is a common finding from 9 weeks onwards.⁷⁴ Tricuspid regurgitation is commonly found in the first trimester, and is thought to be more common in fetuses suffering from aneuploidy, particularly trisomy 21. It has been incorporated into early screening programmes, and is used to adjust the age-related risk for trisomy 21.⁷⁵ It is not clear why tricuspid regurgitation is more common in these fetuses, but it may be associated with delayed development of the atrioventricular cushions, as it resolves spontaneously in most cases, and has no physiological consequences later in pregnancy or after birth. Most cases of tricuspid regurgitation reported in later gestation are also transient and trivial. They are associated with a normal outcome.⁷⁶

In the absence of an obstructed right ventricular outflow tract, non-invasive estimates of the systemic fetal pressures can be estimated from the peak velocity of the jet of tricuspid regurgitation. Important tricuspid regurgitation is holosystolic, often with increased duration of the systolic Doppler envelope, with a compensatory shortening of the diastolic filling time. It may be associated with abnormal waveforms in the peripheral arterial and venous circulations, for example reversal of flow in the venous duct at end-diastole.

DEVELOPMENTAL CHANGES IN SYSTOLIC FUNCTION

In common with observations in more mature fetuses, mean velocities through the outflow tract increase with gestational age. Isovolumic relaxation and contraction times decrease, thus improving the cardiac function. The second half of pregnancy is associated with a rising ventricular stroke volume, and reduction in afterload, which affects the left side more than the right. The peak velocities in the ascending aorta are generally higher than in the pulmonary trunk, and a linear increase with increasing gestation is observed in cross sectional studies.

Cardiac output is traditionally calculated from the right and left ventricles using the velocity time integral of the maximum velocity envelopes through the valves, and a static assessment of valvar diameter measured at the hinge-points. The mean total cardiac output calculated in this way is approximately 550 mL/min/kg body weight. Various investigations in humans, supported by animal data, have shown right cardiac output to be greater than left by at least two-fifths. The major source of error in the calculation of cardiac output results from measurement error of the diameter of the vessel, particularly for clinical studies, and failure to account for pulsatility of the vessel in the equation. In one study, the upper 95% confidence limits for intraobserver variation were reduced to 0.04 mm and 0.09 mm for diameters of 0.6 mm and 6 mm, respectively, by making six repeated measurements of the vessel.⁷⁷

DEVELOPMENTAL CHANGES IN DIASTOLIC FUNCTION

Atrial pressure exceeds ventricular pressure throughout filling, and from early gestation there is a clear distinction between passive and active filling, referred to as the E and A waves, respectively.⁵ The active velocities are higher than passive

Figure 5-11 Doppler recording of abnormal coronary blood flow in a fetus with pulmonary atresia with intact ventricular septum and a right coronary artery to right ventricle fistula. The trace shows high-velocity reversal of flow along the right coronary artery at 2.9 m/sec and normal velocity forward flow.

velocities in the fetus and in the newborn period, resulting in a ratio between the E and A waves which is below 1 in the normal fetus. This ratio, nonetheless, is highly dependent on preload. It cannot provide a load-independent assessment of ventricular function. It is, therefore, a particularly unsuitable measure in fetal life, when direct pressures cannot easily be measured. The patterns of ventricular filling change with age, with a relative increase in early diastolic filling, represented by the E wave, compared with the late diastolic component, or A wave, reflecting increasing ventricular compliance.^{78–80} Reference ranges between 8 and 20 weeks of gestation show a greater volume of flow passing through the tricuspid than mitral valve at all gestational ages. Maturation changes in ventricular properties in human fetuses accelerate after mid-gestation as diastolic filling increases mainly after 25 weeks. They are associated with a decrease in the ratio of the area of the myocardial wall to the end-diastolic diameter of the left ventricle. Thus, the decrease in left ventricular wall mass related to gestational age may be one important mechanism responsible for the alterations in diastolic properties noted in the fetal heart. These are co-incident with the reduction in placental impedance associated with normal adaptation of the spiral arteries.^{81,32}

METHODS FOR NON-INVASIVE FUNCTIONAL ASSESSMENT OF THE FETAL HEART

Diastolic function of the fetal ventricles may be examined using pulsed wave Doppler, but results thus far have prompted differing conclusions. Longitudinal studies have shown that peak E and A waves both increase with gestational age, reflecting the increasing preload of the normally growing fetus, and also, more speculatively, improved maturation of ventricular function.^{82–84} Some studies have reported a similar gestational increase in the waves across the mitral valve, resulting in no significant change in the ratio between them in individuals studied longitudinally.⁸² A significant increase was found, however, in the ratio of the waves through the tricuspid valve in both normal and growth-restricted fetuses.⁸³ An alternative parameter, the velocity–time integral of flow into the ventricles during early and late diastole, has been thought to reflect more accurately changes in diastole. The ratio of the velocity time integral of the A wave to the total velocity time integral has been evaluated,⁸² but no significant change was found, implying no change in diastolic function with increasing gestation. Others, however, have suggested there is an increase in right ventricular compliance.^{83,85} Differences between studies may be explained, in part, by the imprecise nature and variability of these parameters, and the fact that they are poor reflectors of ventricular diastolic function. Furthermore, studies have failed to correlate changes in downstream impedance with patterns of ventricular filling.⁸⁶ Better methods may include measurement of long-axis function of the fetal heart using amplitude of displacement of the atrioventricular ring, and Doppler tissue velocities.

The Tei Index

First described in 1997 from measurements made in adult hearts,⁸⁷ the Tei index has been used in fetal echocardiography to describe changes in myocardial performance with

Figure 5-12 Doppler recording of simultaneous inflow into the left ventricle and flow through the aortic valve. The Tei index is calculated as shown in the figure, measurement a includes the isovolumic acceleration and relaxation times. The ratio of these to the ejection period gives the Tei or myocardial performance index. The higher this is, the worse the myocardial performance.

gestational age, and in conditions of altered loading such as twin-twin transfusion syndrome.^{88–90} This index uses pulsed wave Doppler of the mitral inflow and aortic outflow waveforms. It is technically easy to record and reproducible in serial examination of the fetus (Fig. 5-12), particularly when modified by using the valvar ejection clicks,⁸⁸ and by other authors using myocardial tissue velocities to produce a Doppler tissue Tei index.⁹¹ A reduction in the index is seen with increasing gestational age due to a reduction in isovolumic contraction and relaxation times. Although it has been shown ineffective in animal models to reflect global myocardial function, it is sensitive to afterload changes and fetal conditions complicated by differential loading can be predicted and monitored using this technique.^{89,90}

Long-axis Function of the Fetal Heart

M-Mode Measures of Displacement of the Atrioventricular Ring
The pattern of arrangement of myocytes differs in the right and left ventricles, with the right ventricle lacking myocytes aggregated in circular fashion.⁹² The myocytes aggregated in longitudinal fashion lie predominantly in the ventricular subendocardium, and are affected first by ischaemia.

It is difficult to assess right ventricular function in the minor axis because of poor detection of the endocardial borders, but in adults with heart failure, assessment of the amplitude in the long axis predicts exercise tolerance and survival.^{93,94} Displacement of the atrioventricular ring is assessed using M-mode techniques, and reflects shortening of the myocytes aggregated in longitudinal fashion towards the apex of the ventricle in systole, and their retraction in diastole. In common with evaluation of long-axis function in the adult, M-mode measurements of amplitude of displacement of the atrioventricular ring can be made in the human fetus. The methodology is simple and reliable, and normal reference ranges have been described in the fetus and adult.^{95,96} These show age-related increases in amplitude of displacement in the fetus, confirming right ventricular dominance as the right ventricular free wall shows increased displacement compared to the left or the ventricular septum.

Doppler Tissue Imaging

New Doppler imaging technologies are available to assess myocardial function, and are widely used in the assessment of the adult heart. Most of these modalities have been tested in the fetus. Some are suitable, and may increase our knowledge of maturation of the myocardium in the normal fetus and in response to pathophysiological situations.

There are, nonetheless, considerable technical limitations in applying all measurement used in adult studies to the smaller fetal heart, where there is no electronic gating and smaller tissue volumes. All Doppler modalities require high frame rates, with 200 Hz being ideal, and must be closely aligned parallel to the mural motion, ideally below 20 degrees. Accuracy of measurement requires that the sample volume is small, and velocity limits reduced to optimise the trace.

Pulsed Doppler Assessment of Long-axis Function

The simplest method in use to assess long-axis function is pulsed Doppler assessment of myocardial tissue Doppler velocities at the atrioventricular ring. These reflect shortening and lengthening velocities of the myocytes aggregated in longitudinal orientation. Ventricular long-axis shortening velocities and amplitude correlate with overall ventricular function as assessed by ejection fraction, and early and late diastolic lengthening velocities correlate with ventricular filling velocities assessed by Doppler. Reference ranges have been created in the normal fetal heart, and gestationally related values show similar increases,^{95,97,98} albeit that those recorded using spectral Doppler tissue were up to one-fifth lower than those obtained in other studies (Fig. 5-13).⁹⁹

Pulsed Doppler and M-mode measures allow quantification of long-axis cardiac function in pregnancies complicated by maternal disease, such as diabetes mellitus. Studies have reported a relationship between maternal concentrations of haemoglobin A1c in diabetic women and cardiac function in their fetuses.¹⁰⁰ Although free wall and septal hypertrophy was observed in the fetuses of diabetic

mothers from the second trimester, this was accompanied by increased function, suggesting adaptive hypertrophy rather than the presence of a cardiomyopathy.

Colour Doppler Myocardial Imaging

Colour Doppler myocardial imaging¹⁰¹ provides measurements of myocardial motion and deformation from which myocardial strain and strain rate can be calculated. This technology is based on the differences of tissue Doppler velocities in adjacent myocardial points from which strain rate and strain is estimated. This shows the extent of torsion and twist of the heart during the normal cardiac cycle. The technique is particularly useful following myocardial infarction in the adult, as it enables regional abnormalities to be detected. Strain rate has been recorded in small numbers of children with aortic valvar atresia, and in those with hypoplastic left heart syndrome.^{102,103} There are particular technological difficulties using this approach in the fetus, relating to the small myocardial mass interrogated by each pixel, and also to the fact that myocytes are aligned longitudinally in the fetal right ventricle, but circumferentially in the fetal left ventricle. Doppler velocity colour coding permits the detection of motion of the aortic wall, and measurement of the velocity of the pulse wave. This technique may prove to be a useful non-invasive technique to assess fetal arterial compliance.

Speckle Tracking

Cardiac torsion and twist have been investigated using a non-Doppler method based on speckle tracking. This methodology works by tracking bright myocardial echoes, and is relatively angle independent. It has been evaluated against sonomicrometry in animal models and is currently in clinical use in the adult, where its ability to demonstrate motion of the heart during systole and diastole has been compared to magnetic resonance imaging. The method is under evaluation in the fetus, but published studies so far have insufficient power to create normal reference ranges in the fetus, and reproducibility is rather limited. Preliminary reports have shown a gestational increase in velocities, but no change in strain or strain rate. The angle independence is likely to be useful in examination of the fetal heart provided frame rates analysable by the software can be improved.

Figure 5-13 Graphs plotting gestation changes in mean or median tissue Doppler velocities of the E wave (Ea) at the base of the heart with the gate placed at the right ventricular free wall (RV), left ventricular free wall (LV), and interventricular septum (IVS): Those measured using spectral tissue Doppler were consistently 15% to 20% lower.

METHODS FOR ASSESSING VASCULAR PHYSIOLOGY AND VOLUME OF BLOOD

Measurement of Volumes of Flow of Blood

Accurate measurement of volumes of flow in peripheral vessels is of clinical interest because it reflects differential perfusion of organs in the fetus, both during normal growth and in response to adverse circumstances. Data on placental and cardiovascular flow and function in the human fetus are more difficult to collect and to verify than in the chick embryo and ovine models because they have to be collected non-invasively. Flow of blood can, of course, be measured with a high degree of accuracy with electromagnetic¹⁰⁴ or transit-time flowmeters.¹⁰⁵ Since these methods require an invasive approach, they cannot currently be applied in studies on human fetuses. Non-invasive methods to measure the volume of flow in the aorta are confounded by methodological difficulties, mostly in relation to accurate measurements of aortic diameter, an issue that

has still not been resolved, despite improvements in the resolution of ultrasound.^{77,106}

The method traditionally used to estimate volume of flow in a vessel is from the product of the velocity time integral of the Doppler signal in the vessel, the heart rate and a separate estimation of the area of the lumen from static measurements of its diameter. The inherent error in this method is estimated to be as large as one-fifth when measuring fetal arteries.⁷⁷ This error mostly results from limits of resolution of the diameter, but failure to account for changes in pulsatile flow may account for almost one-tenth of the difference in volume of flow compared with static assessment.¹⁰⁷ Estimations of venous flow have been reported,¹⁰⁸ but the potential error is further compounded by the assumption that the vessel under examination is circular.

Simultaneous measurement of the diameter of the pulsatile vessel and the mean velocity of flow allows an estimate of flow volume in the descending aorta of the healthy fetus.¹⁰⁶ The volume of aortic flow, measured in this way, has shown a linear increase with increasing gestation, being estimated at 225 mL/min/kg body weight in fetuses of 250 days.

Estimation of Perfusion Using Power Doppler

Methods using newer Doppler modalities have been evaluated as surrogate estimates of perfusion. Power Doppler was initially investigated as a method to estimate perfusion in the adult, but an important methodological problem was the formation of rouleaux that artificially elevated the maximal value for power Doppler amplitude. Fortunately, studies in the fetus confirm that fetal blood does not form rouleaux to any significant degree, so permitting a comparison of perfusion of different organs. Studies using quantification of power Doppler have suggested an increase in power Doppler signals from the placenta, lungs, spleen, liver and kidney up to 34 weeks of gestation, following by a decrease in all but the spleen, which remains constant. Abnormalities in the ratio of volumes in the brain and lungs were seen in high-risk pregnancies, but methodological problems using this technique may limit the conclusions drawn by such studies. Mean pixel intensity has been the traditional method of assessment of perfusion over a region of interest, but this methodology is dependent not only on the volume of flow of blood, but also depth, gain and attenuation in overlying layers of tissue.

An alternative method, the fractional moving volume, attempts to compensate for these confounding variables.^{109,110} When power Doppler is applied to a region, the centre of a large fetal vessel, such as the aorta, is interrogated and assigned a value of 100% amplitude. This can be used to compare the amplitude in smaller vessels, such as those supplying the fetal kidney.¹¹¹ There are pitfalls with all imaging methods, and those limiting the reliability of the technique of the fractional moving blood volume include the depth of the imaged organ from the transducer. Phantom studies describe that the power is linearly related to velocity over a limited range, suggesting it may be useful to discriminate between normal and decreased fetal perfusion in organs such as the lung. Validation of measurements with power Doppler ultrasound has been performed in sheep using radioactive microspheres, showing good correlations in the adrenal gland.¹¹² Power Doppler methods may be improved by combining them with

three-dimensional standardised techniques in order to identify a reproducible anatomical plane for measurement.¹¹³

Three- and Four-Dimensional Echocardiography

All imaging techniques depend on excellent quality of imaging, so the three-dimensional picture is only as good as the cross sectional image, and quality may be compromised by fetal movements and maternal respiration. Additionally the development of these techniques have been hampered until relatively recently by the lack of electrocardiographic gating of the fetal heart. New technology that allows live real-time three-dimensional imaging is promising, and has been reported by several groups. These techniques have been used for imaging of the fetal heart for diagnostic purposes, using technology such as spatial temporal methodology that allows the rapid acquisition of a three dimensional volume set which can be manipulated later off-line. This has potential in training and evaluation of cardiac abnormalities remotely, as the volume sets can be sent electronically for expert analysis.¹¹⁴

Three-Dimensional Quantification of Volume and Ejection Fraction

Physiological information is limited, but three-dimensional inversion mode sonography has been used to establish normal ranges for ventricular volumes and ejection fractions.⁴⁰ This may prove to be a useful methodology in the assessment of ventricular size in structural heart disease.

Fetal Vascular Physiology

Arterial Physiology

The role of the endothelium in modulating vascular responses is well recognised. A series of studies performed in children and young adults with risk factors for later disease have shown that it is possible to detect abnormalities in vascular responses to stimuli both dependent and independent of the endothelium before there are signs of overt disease.^{115–117} While it is not yet possible to examine directly the responses of the fetal endothelium in this way, information is available on the pulsations of the vessel wall and the velocity of the pulse wave of the fetal aorta, which have been measured using wall-tracking devices. Pulsations of the arterial wall (Fig. 5-14) reflect impedance from distal vascular beds along the fetal arterial tree. The pulsatile change in cross sectional area of the fetal aorta during the cardiac cycle at the 20th week of gestation is approximately 22%, falling to 17% at term compared with about 9% in the adult aorta.¹¹⁸ This may reflect a reduction

Figure 5-14 Diagram of the arterial pulse waveform, illustrating the maximum incremental velocity (MIV), the relative pulse amplitude (ΔD), and the late decremental velocity (LDV). Ddiast, diastolic diameter of the vessel; Tprop, propagation time of the pulse wave.

in arterial mural compliance with increasing blood pressure in the growing fetus, and with structural changes within the vessel wall, which alter its physical properties. Information about the fetal vascular tree may be gained from analysis of the separate parts of the wall as it moves. Studies using a feline model have correlated the diameter of the movements of the pulsating wall with invasive measures of ventricular function and afterload¹¹⁹ and found the maximal incremental velocity to be the best single variable, reflecting total peripheral resistance and late decremental velocity better to reflect a lower stroke volume and reduced cardiac output. The maximum incremental velocity of the arterial pulse waveform (see Fig. 5-14) may provide additional information on ventriculo-vascular coupling in the fetal circulation. Standard arterial Doppler assessment using the ratio of acceleration to ejection periods at the level of the arterial valve is said to reflect the mean arterial pressure in that artery, and also to reflect on the ventricular function. Unfortunately, this has not proved to be reliable.¹²⁰ In contrast, the maximum incremental velocity has been shown in animal studies to correlate well with the acceleration in aortic flow, and with the rate of rise of left ventricular pressure.¹¹⁹ The rate of increase in the aortic diameter in early systole is dependent on ventricular systolic function but is dependent also on distal impedance. If this can be considered to remain relatively constant for a single examination, then maximum incremental velocity may be a better non-invasive indicator of ventriculo-vascular coupling than currently available Doppler measures.

Venous Physiology

The venous system is considerably more pulsatile in the fetus than after birth. Pulsations of the wall of the inferior caval vein reflect not only the fetal central venous pressure, but also the changes in ventricular relaxation and filling. Because of the parallel arrangement of the circulation, venous pulsations also reflect the distal arterial impedance. The information derived has provided interesting physiological insights into fetal circulatory development.^{118,121} In contrast to the arterial system, the relative pulse amplitude of the inferior caval vein increases with gestation.¹²¹ The relative gestational increase in venous pulse amplitude may reflect an improvement in the filling and emptying of the right ventricle. This is supported by the findings, using Doppler, of a reduction in reversal of flow of blood away from the heart in the inferior caval vein of the healthy fetus.⁵¹ That veno-ventricular coupling is further improved is suggested by the finding of forward diastolic flow in the pulmonary trunk in normally growing fetuses with increased venous mural pulsatility.¹¹⁸ Diastolic flow in the pulmonary trunk has been reported in association with a restrictive right ventricle in children following repair of tetralogy of Fallot,¹²² but these fetal Doppler indexes suggest that diastolic filling of the right ventricle improves with gestation. The Doppler findings suggest that improved filling is a consequence of reduced distal impedance drawing blood into the arterial duct at the end of diastole, before the valve opens fully.^{123,124} Venous mural pulsations, therefore, may reflect the falling impedance of the arterial tree distal to the arterial duct, as well as improving cardiac compliance (Fig. 5-15).

Pulsed Wave Velocity

Measurement of compliance or elastance of a blood vessel may be determined from the speed of propagation of a pulse travelling in its wall: The faster the velocity, the stiffer the wall. Such velocity has been shown to increase by about 1 m/sec in chick embryos from stage 18 to 29,¹²⁵

Figure 5-15 Doppler recording of flow through the pulmonary valve. Forward flow (FF) at end diastole is frequently seen in the normal fetal heart.

and in normal fetuses from 20 weeks to term.¹¹⁸ The velocity depends on the mean distending pressure of the vessel, coupled with changes in the composition of the wall. The mean aortic blood pressure increases during gestation, as does the thickness of the aortic wall relative to the lumen and the supporting adventitial tissue. The composition of the wall changes with accelerated deposition of elastin during the last weeks of gestation. This continues during the first months of life and confers increased distensibility to the aorta.¹²⁶ The velocity of the pulse wave has been shown to increase with age, and is an important determinant of coronary arterial flow and left ventricular function.¹²⁷ It has also been shown to correlate with atherosclerosis and to be increased in coronary arterial disease.¹²⁸ Reduced arterial distensibility contributes to the pathogenesis of hypertension. A reduction in the arterial characteristic impedance results in increased pulse pressure, and the pulsatile cardiac workload is accentuated. Furthermore, the resultant increase in the velocity of the pulse wave results in early return of the reflected wave and further augments the systolic pressure.

Ventriculo-vascular Coupling

Fetal Systemic Pressures

Direct measurements of intraventricular pressure have been made in the normal heart between 18 and 29 weeks of gestation.¹²⁹ This study confirmed that ventricular systolic pressures increase with gestation. In fetuses in which it was possible to record measurements in both ventricles, the pressures were equal. End-diastolic pressures that have previously only been inferred from Doppler assessment were directly measured (Fig. 5-16).

Pressure-Volume Loops

Pressure-volume loops remain the gold standard for measuring ventricular function independently of load, but their measurement is invasive. It is possible to construct pressure-volume loops in the chick embryo (Fig. 5-17).¹ Physiological differences have been demonstrated between right and left ventricular function in the postnatal dog.¹³⁰ The shape of the pressure-volume relationship of the right ventricle differs in several ways from that of the left ventricle

Figure 5-16 Pressure traces showing the systolic and end-diastolic measurements within the human fetal ventricle at 22 weeks of gestation for (A) the left ventricle and (B) the right ventricle. (Reproduced by permission of Heart from Johnson P, Maxwell DJ, Tynan MJ, Allan LD: Intracardiac pressures in the human fetus. *Heart* 2000;84:59–63.)

(Fig. 5-18). Right ventricular ejection occurs long after peak pressure has been achieved, and, for a given intraventricular volume, the pressure is less in the right ventricle.¹³¹ The instantaneous pressure–volume relationship at end-systole is linear in both ventricles, but the correction volume, as defined by the intercept of this line with the x axis, is constant in the left ventricle. It does not change with contractile state, in contrast to that of the right ventricle.¹³⁰

Similar assessment of the pressure–volume relationships, independent of load, is not yet technically possible in the healthy human fetus. Non-invasive insights into normal cardiovascular physiological development, however, have

been obtained using echo-tracking equipment and Doppler ultrasound tissue imaging. Although the right ventricle deals with a greater volume load in fetal life than does the left ventricle, minor-axis ventricular systolic function and simultaneous direct pressure measurements are similar in right and left ventricles before birth.¹²⁹ More recently, studies of fetal long-axis function have reported that myocardial velocities and amplitude of motion are increased in the right ventricular free wall compared to the left or the ventricular septum.^{95,97–99} This may be in response to the increased volume loading of the right ventricle compared with the left ventricle during normal maturation, and the increased number of myocytes aligned in longitudinal fashion. The relative volume loading of the right ventricle during fetal life may alter the deposition, or cause the re-expression of, essential cytoskeletal and certain heat shock proteins such as desmin, the cytokeratins, vimentin, and HSP-72. These have been described in conditions of volume and pressure loading of ventricles postnatally, and may act adversely, altering responses in the postnatal situation, thus permitting the ventricle to dilate more readily in response to volume and pressure loads, and so further prejudice its function.

Heart Rate Variability

The variability in heart rate is determined by the maturation of the autonomic system. There are major differences between species in the time at which the balance between neurotransmission of the sympathetic and parasympathetic system is accomplished. This is related to the independence of the individual species before and immediately after birth. Maladaptation, or immaturity, of neural control may manifest in acute life-threatening events in infancy. Antenatal assessment has been difficult, as measurement of beat-to-beat measurements has not been possible with existing technology such as the cardiotocograph.

Figure 5-17 Pressure–volume loops in a stage 21 chick embryo measured during preload infusion. (With permission from Keller BB: Maturation/coupling of the embryonic cardiovascular system. In Clarke EB, Markwald RR, Takao A [eds]: *Developmental Mechanisms of Heart Disease*. Armonk, NY: Futura, 1995, p 375.)

Figure 5-18 Pressure-volume loops of the right (A) and left (B) ventricles in a canine model illustrating the differences in the end-systolic pressure-volume relationship. The instantaneous pressure-volume ratio of the canine left ventricle is independent of load and is altered by adrenaline and by the heart rate. The correction volume (V_d) is constant. (A, With permission from Maughan WL, Shoukas AA, Sagawa K, Weisfeldt ML: Instantaneous pressure-volume relationship of the canine right ventricle. *Circ Res* 1979;44:309–315; B with permission from Suga H, Sagawa K, Shoukas AA: Load independence of the instantaneous pressure-volume ratio of the canine left ventricle and effects of epinephrine and heart rate on the ratio. *Circ Res* 1973;32:314–322.)

The full electrocardiogram can be recorded by use of scalp electrodes, but only once rupture of membranes has occurred. This has provided useful information during labour by analysing the ST waves.¹³² Non-invasive recordings of the full fetal electrocardiogram can now be obtained from 15 weeks of gestation in the human fetus using newer techniques. These include blind signal separation from signals obtained from electrodes placed on the maternal abdomen, and magnetocardiography (Figs. 5-19 and 5-20). These studies have described reference ranges for time intervals in the fetus.¹³³ Use of the techniques has permitted more detailed analysis of fetal arrhythmias.^{134–136} Variability may also be described using the standard deviation from the time domain, as well as other measures from the frequency domains and approximate entropy as a measure of complexity.¹³⁷ Two distinct fractal structures have been identified within this variation. They show significant gestational change in the normal fetus, and may be useful to evaluate variation in disease states.¹³⁸ Investigation into variability of the heart rate in the fetus and neonate may provide insights into developmental processes in health and disease, and refine stratification of fetuses at risk of intra-uterine death, as well as the risk of sudden infant death syndrome in those born prior to term. Neonates who have suffered apparent life-threatening events show differences in heart rate variability, suggesting altered autonomic control.^{139,140}

Vascular Programming

The fetal origins hypothesis proposes that adaptation of the fetus to its intra-uterine environment and postnatal stressors may have life-long consequences, and that the fetal response to an environmental challenge may result in programming of different organs, depending on the timing of the insult. Restricted growth in the last trimester of pregnancy has been associated with later cardiovascular disease. The original concept of fetal programming has been expanded, and now encompasses both pre- and postnatal adaptation under the umbrella of the 'Developmental Origins of Health and Disease', known also by the acronym DOHaD. Environmental factors may also contribute to permanent effects resulting from altered epigenetic genetic regulation, and this has created a new field of epigenetic epidemiology.¹⁴¹

Fetal ECG Report

Name: QC50 Date: 18/7/2001
 Singleton Gestation: 35 weeks
 No. of sensors 12 Length of dataset: 57.9 seconds
 Data used: 57.9 seconds - from 0 to 57.9 seconds
 Pass band from 1 to 150 Hz
 Mean heartrate: 153 bpm
 Max heartrate: 157 bpm
 Min heartrate: 146 bpm

Rhythm strip trace 1: from 0 sec to 3 sec

Figure 5-19 An example of a report on a fetal electrocardiogram from a singleton pregnancy at 35 weeks gestation. (Reproduced by permission of the British Journal of Obstetrics and Gynaecology, and the authors of reference #132.)

Figure 5-20 Representative averaged magnetoecardiographic waveforms recorded during fetal life. **A**, A normal fetus at 39 weeks gestation. **B**, A normal fetus, but at 37 weeks gestation. **C**, Recordings from a fetus of 27 weeks gestation, but suffering ventricular tachycardia (VT) at 25 weeks gestation. **D**, A fetus of 27 weeks gestation with supraventricular tachycardia (SVT). **E**, A fetus, again with supraventricular tachycardia, at 31 weeks gestation. **F**, The fetus illustrated in panel C, but this panel reveals the tachycardia present at 25 weeks gestation. **G** and **H**, Fetuses with complete atrioventricular block (CAVB) at 30 and 25 weeks gestation, respectively. **I**, A fetus with blocked premature atrial contractions (PACs) at 20 weeks gestation. All waveforms are taken from the channel with the largest signal amplitude, the amplitude being shown in units of femtotesla, with each femtotesla equal to 10^{-5} tesla. (The image is reproduced by permission of the authors of reference #134.)

Vascular Programming in the Setting of Restricted Growth

The fetal cardiovascular system differs from that of the neonate in that the interdependence between cardiac and pulmonary physiology is less important than that of the placental vasculature. Normal placental development includes appropriate trophoblastic invasion to remodel placental spiral arteries and create a low impedance circulation. This is important in the development of normal fetal cardiovascular responses.³² This vascular change does not occur in cases of placental dysfunction. The reduction in placental flow may then result in a growth-restricted fetus.^{44,45} The fetus alters its adaptive responses to enable survival in these adverse conditions, sometimes to the detriment of later functional and adaptive responses.⁴⁶ These have been termed predictive adaptive responses.¹⁴² This model proposes that the risk of disease depends on the degree of mismatch between the predicted postnatal environment and that which exists. The prediction usually anticipates a worse outcome than exists, which further increases the mismatch. Adverse early influences are thought to result in the so-called thrifty phenotype. This describes an individual that can match supply and demand successfully to permit survival, even though

some of the adaptive mechanisms this involves may lead to later disease through disturbances of normal cardiovascular and neuro-hormonal control mechanisms. Postnatal nutrition often results in catch-up growth in growth-restricted infants, and this may further disturb the thrifty phenotype, leading to further adaptations to permit an individual to live within his or her predicted environment.

Many Doppler ultrasound studies of the growth-restricted fetus have been published. Ventricular diastolic filling is lower than normal. The increased systemic impedance, due to placental dysfunction, results in an impairment of venous flow towards the heart during diastole, with a consequent reduction of peak velocity of inward flow^{51,52} and a reduction in the pulsations of the wall of the inferior caval vein. The increased central venous pressure may contribute to impairment of systemic venous return and a reduction in normal forward flow during late diastole in the pulmonary trunk. This suggests that there is abnormal veno-ventricular-vascular coupling.⁸³ Increased shunting through the venous duct in growth-restricted fetuses reduces umbilical blood supply to the fetal liver, which may be detrimental in those surviving with

restricted growth.¹⁴³ Occlusion of the venous duct leads to a significant increase in cell proliferation in fetal skeletal muscle, heart, kidneys, and liver and possibly to an increase in expression of IgF1 and 2 and mRNA. These alterations may have a significant long-term influence on metabolism in the growth-restricted individual, lending support to the concept of altered metabolism seen in adults with reduced birth weight.¹⁴⁴

Some studies have reported a reduction in systolic velocities through the arterial valves in growth-restricted fetuses. This is not a universal finding, however, and does not necessarily reflect poor ventricular function. Other authors have reported increased peak systolic velocities of flow, but found that the flow commenced later in systole than normal, thus resulting in an increased pre-ejection period and a shorter ejection time because of the increased systemic impedance, resulting in a reduced stroke volume.¹⁴⁵ Cardiac output corrected for weight is normal in growth-restricted fetuses, but the mean velocity of flow in the descending aorta is significantly less, and the volume of blood flowing showed a similar, but non-significant trend, suggesting more is directed cephalad.⁸³

The effects of vascular programming associated with altered intra-uterine nutrition may not be obvious in individuals studied early in life. While component parts of the fetal arterial pulse waveform are significantly different in the growth-restricted fetus, no differences have been found in pulsed wave velocity.⁸³ The relationship between pulsed wave velocity and intra-uterine growth restriction is not yet clear, but in babies delivered at normal term, there appears to be an inverse association between the velocity of the neonatal arterial pulse wave and maternal systolic blood pressure, with a positive relationship for neonatal gestational age, birth weight, length, and neonatal blood pressure.¹⁴⁶ Prematurity alone does not appear to influence later the velocity of the pulse wave. Children born prior to term with a Z-score for birthweight below -2 SD had significantly higher mean blood pressure and higher pulse-wave velocity at school age than those born prior to term, but of normal weight.¹⁴⁷ Longitudinal studies have shown that young adults studied in fetal life because of restricted growth have smaller aortas than controls, and higher resting heart rates.¹⁴⁸ It may be that maturation of the aortic wall is required. Alternatively, a process of amplification¹⁴⁹ may need to occur during infancy before any differences can be appreciated in the properties of the aortic wall.

Vascular Programming in Twin-Twin Transfusion Syndrome

Twin-twin transfusion syndrome is an extreme model of circulatory imbalance occurring in monochorionic pregnancies where there are two genetically identical individuals. Within-pair responses in the cardiovascular response to differences in volume load and the effect of increased placental resistance can be measured. Studies have confirmed that fetal vascular programming occurs and reduced arterial distensibility is detectable in the growth-restricted donor twin during infancy.¹⁵⁰ Furthermore the inter-twin differences are altered by intra-uterine laser ablation of placental vascular anastomoses in the second trimester of pregnancy.¹⁵¹

Vascular Programming Following Fetal Coarctation

Coarctation of the aorta can be present in the fetus. Both a hypoplastic arch, and a coarctation shelf, can be visualised and quantified using ultrasound.³⁸ A continuous

Figure 5-21 A, A coarctation shelf (CoA) can be visualised in the fetus using ultrasound. B, A continuous Doppler pattern of flow in the isthmus may be recorded, that reflects altered patterns of flow which confirms arch obstruction in fetal life.

Doppler pattern of flow in the isthmus may be recorded, and reflects altered patterns of flow which confirm obstruction (Fig. 5-21). Studies of endothelial function in normotensive young adults undergoing repair of the coarctation as neonates and infants have demonstrated reduced endothelial-dependent and -independent function confined to the pre-coarctation site compared with normal controls, suggesting that early alteration of flow in fetal life may programme later function in spite of early and adequate surgical repair.^{115,149,152}

SUMMARY

The ability to examine the physiology of the developing circulation in the human fetus non-invasively has become a reality. It provides us with the opportunity to compare developmental changes in the human with those of other species, thereby ensuring that we do not accord unquestioningly human cardiovascular development with those attributes found previously in other species using invasive methods.

Doppler ultrasound technology has enabled serial examination of the human fetus from the first trimester allowing us to observe non-invasively developmental changes in diastolic and systolic function, myocardial maturation and the responses to structural and functional disease states. More quantitative measures of perfusion, volume flow and ventricular volumes enable a better appreciation of cardiac output and organ flows in the early human fetus.

The importance of the development of the arterial tree can be examined by pulsed wave velocity and measures of endothelial function in conduit arteries. There is

a convincing body of evidence that suggests early changes in volume flows and the response of the arterial wall may initiate permanent structural changes that may lead to longer term pathology such as hypertension. Early detection of vascular abnormalities may permit interventional strategies before birth and in childhood that could reverse the progression to clinically important disease in fetuses identified as being at high risk.

ACKNOWLEDGEMENT

I am grateful to Dr Constancio Medrano for permitting me to adapt his graphic of long-axis function presented at the meeting of the Association for European Paediatric Cardiology held in Warsaw in May, 2007 for Figure 5-13.

Systemic Circulation

YIU-FAI CHEUNG

The systemic circulation refers to the circulation in which blood is carried from the systemic ventricle, which is the left ventricle in the setting of ventriculo-arterial concordance, through a network of arteries and arterioles to the tissue capillaries, and drained via the systemic venous system to the systemic venous atrium.

The systemic arterial system serves two important functions. First, it acts as a low-resistance conduit through which blood is distributed to different parts of the body. Second, the arterial tree buffers the pulsatile pressure to convert systemic ventricular pulsatile ejection into a steady stream of capillary flow. Additionally, the endothelium, which lines the vascular lumen, exerts important vascular homeostatic effects through production of a variety of substances. Hence, alterations of the mechanical properties of the arterial wall and function of the endothelium have significant implications on normal functioning of the systemic arterial system. Furthermore, optimal performance of the systemic ventricle depends on its favorable interaction with the systemic circulation. In the setting of congenital heart disease, the systemic ventricle may be a morphological left ventricle, morphological right ventricle, or single functional ventricular chamber of right, left or indeterminate morphology. As a result of systemic arterial dysfunction, an unfavorable ventriculo-arterial interaction may result. On the other hand, systemic ventricular dysfunction may also predispose to systemic arterial dysfunction.

In this chapter, the systemic circulation is discussed from structural, physiological, and mechanical perspectives. Measures of arterial function and paediatric conditions associated with systemic arterial dysfunction are then highlighted. Finally, the concept of ventriculo-arterial interaction and its relevance in congenital and acquired heart disease in the young are described. The systemic venous system is discussed in Chapter 23.

SYSTEMIC ARTERIAL SYSTEM

Structure

The systemic arterial tree begins with the aorta, the largest arterial trunk that arises from the left ventricle. The aorta ramifies into tributaries to perfuse all parts of the body, with the exception of hair, nails, epidermis, cartilage, and cornea. The large central arteries are protected within the thoracic and abdominal cavities, while peripheral conduit arteries run along the flexor surfaces in the upper and lower limbs where they are less exposed to injury. The fashion in which the arterial tree ramifies varies: an arterial trunk may give off several branches in succession and continue as a main trunk, give off a short trunk that subdivides into

several branches, or bifurcate at its distal end. The ascending aorta arises at the base of the left ventricle and gives off the first branches, the right and left coronary arteries. It continues as the aortic arch, from which the brachiocephalic, left common carotid, and left subclavian arteries arise. The thoracic descending aorta begins as a continuation of the aortic arch and penetrates the diaphragm to continue as the abdominal descending aorta. The celiac trunk and superior and inferior mesenteric arteries arise from the abdominal descending aorta to supply the liver and gastrointestinal tract, while the renal arteries branch off at right angles to perfuse the kidneys. The descending aorta bifurcates at its distal end into the right and left common iliac arteries, the latter bifurcating into the internal iliac artery to supply the pelvic organs and the external iliac artery that continues as the femoral artery to supply the lower limbs. The systemic arterial tree is a tapering branching system. Hence, the aorta tapers from its origin to its termination at the iliac bifurcation and branched daughter vessels are always narrower than the parent vessel, which has implications on wave reflection. The arterial ramifications end in arterioles, which then usually continue as capillaries. Beyond the major arterial branches, the total cross sectional area increases progressively to the capillary bed. Apart from size, the proportion of cellular and structural components also varies along the arterial tree. Notwithstanding these variations, the arterial wall is made up of three constant layers: an internal tunica intima, a tunica media, and an external tunica adventitia.

The intima comprises the endothelium, a subendothelial layer, and an elastic membrane. The endothelium consists of a monolayer of cells that line the vascular lumen. Apart from forming a physical barrier between the circulating blood components and the vascular wall, the endothelial cells play a pivotal role in vascular homeostasis. The subendothelial layer is made up of fibroblasts and variable amount of collagen. The internal elastic membrane consists of a network of elastic fibres and forms the boundary with the media.

The media, usually the thickest layer in the arterial wall, is responsible for the mechanical properties of the vessel. Its structural components are vascular smooth muscle cells and extracellular matrix, the latter consisting of elastic lamellas, collagen fibres, structural glycoproteins, and ground substance.¹ While vascular smooth muscle cells maintain vascular tone through contraction and relaxation, the extracellular matrix of the media provides a structural framework for optimal functioning of the blood vessels.

The elastic fibres in the media, arranged in concentric lamellas that form boundaries between layers of vascular

smooth muscle cells, are 90% represented by elastin. Cross-linking of elastin confers to the arteries elasticity, the ability to distend during cardiac systole and recoil during diastole. Elastin has also further been implicated in the control of proliferation and phenotype of smooth muscle cells.² Elastin has an estimated half-life of more than 40 years in humans, and the rate of its synthesis is thought to be negligible in adulthood.^{3–5} Hence, it appears that damaged elastin, as a result of either degeneration or pathological process, is unlikely to be replaced. Other constituents of elastic fibres include microfibrillar-associated glycoproteins and fibrillin.^{6–8} Fibrillin forms a microfibrillar network that serves as scaffolding for deposition of elastin and assembly of elastic fibres. A recently discovered protein, fibulin-5, also plays a critical function during elastic fibre development through its interactions with elastin and integrins.^{9,10} Other structural glycoproteins in the arterial wall include fibronectin, vitronectin, lamin, entactin/nidogen, tenascin, and thrombospondin.^{11,12}

Collagens are composed of three polypeptide α -chains arranged to form a triple helix, which confers tensile strength to the vessel wall. Types I and III collagen are the major fibrillar collagens in blood vessels, constituting about 90% of vascular collagens.¹³ Collagen is the stiffest component of the arterial wall, with an elastic modulus of 10^8 to 10^9 dyne/cm².¹⁴ By contrast, the elastic modulus of elastin is of the order of 10^6 dyne/cm.^{2,15,16} Hence, the absolute and relative quantities of elastin and collagen contribute significantly to stiffness of the arterial wall. The elasticity of the arterial wall is a non-linear function of transmural pressure. To explain the non-linear elasticity, a qualitative model proposes that at low pressure, the tension is borne by elastin, and as the pressure and stretch increase, collagen fibres take on an increasing fraction of the tension with progressive stiffening of the blood vessel, hence preventing its over-distention at high pressure.¹⁷ Indeed, increasing recruitment of collagen fibres in the human brachial artery as transmural arterial pressure increases has been shown *in vivo*.¹⁸ Recent proposed models take into account the contribution of vascular smooth muscle cells, viscoelastic properties of the matrix proteins, residual stresses due to growth and remodeling, and gradual recruitment of collagen fibres with increasing pressure.^{19–22}

The ground substance is filled by proteoglycans. Proteoglycans are macromolecules that possess one or more linear glycosaminoglycan chains linked to a core protein. The proteoglycans in the vessel wall are hyaluronan, versican, biglycan, decorin, lumican, syndecans, fibroglycan, and glypican.²³ The proteoglycans have diverse roles in the organisation of connective tissue structure, regulating cellular activities and metabolism, permeability, filtration, and hydration, and controlling cytokine bioavailability and stability.^{24–27} Different components of the extracellular matrix can be degraded by matrix metalloproteinases. Importantly, matrix metalloproteinases play a fundamental role in the degradation of vascular extracellular matrix²⁸ not only during normal physiological vascular remodeling, but also during pathological remodeling.^{23,29}

The distribution of structural components within the media varies along the arterial tree, hence accounting for the difference in mechanical properties between proximal and distal arteries.³⁰ Of significance is the fall in elastin to collagen ratio and increase in smooth muscle cells with

increasing distance from the heart.^{31,32} Arteries have been categorised as elastic or muscular based on structural composition of the media. Hence, the aorta and its major branches are described as elastic arteries, while brachial and femoral arteries are regarded as muscular conduit arteries. At the arteriolar level, the media consists of essentially one to several layers of smooth muscle cells. Thus, the basic architecture of arteries justifies the division of the systemic arterial tree into a proximal compartment, in which elastin predominates, and a distal compartment, in which collagen and vascular smooth muscle cells predominate.³⁰ Alterations of structural components of the media as a result of degeneration, genetic mutations, or imbalanced activities of metalloproteinases and their inhibitors can have significant impact on the mechanical properties of the vessels.

The adventitia contains mainly fibroblasts and collagen fibres and some elastic fibres. Increasingly, the contribution of adventitial layer to the elastic properties of arteries is recognised.^{33,34} Nutrient vessels, vasa vasorum, arise from a branch of the artery or from a neighbouring vessel to ramify and distribute to the adventitial layer.

Endothelial Function

The endothelium comprises a monolayer of endothelial cells that lines the vascular lumen. It is strategically located between circulating blood components and vascular smooth muscle cells to exert a pivotal role in vascular homeostasis. By producing a wide variety of substances, the endothelium regulates vascular tone, inhibits smooth muscle cell proliferation and migration, controls cellular adhesion, regulates inflammation, and exerts fibrinolytic and antithrombotic actions. In recent years, the concept of endothelial function has extended from the vascular lumen to the vascular wall and adventitia, which are supplied by vasa vasorum considered as an active intravascular micro-circulation.^{35,36}

Nitric oxide, initially identified as the endothelium-derived relaxing factor,³⁷ is the major vasodilating substance released by the endothelium. Nitric oxide is synthesised from L-arginine by the action of endothelial nitric oxide synthase, primarily in response to shear stress produced by blood flow.³⁸ Cofactors including tetrahydrobiopterin and nicotinamide adenine dinucleotide phosphate are involved in nitric oxide production.³⁹ Apart from shear stress, endothelial nitric oxide synthase can also be activated by bradykinin, adenosine, vascular endothelial growth factor, and serotonin.⁴⁰ Asymmetrical dimethylarginine, on the other hand, is an endogenous inhibitor of nitric oxide synthase⁴¹ and has been implicated in the mediation of adverse effects of traditional risk factors on endothelial vasodilator function.⁴² Nitric oxide has a half-life of a few seconds *in vivo*. It diffuses from endothelial cells to exert its relaxation effects on vascular smooth muscle cells by activation of guanylate cyclase, which in turn increases production of cyclic guanosine monophosphate and leads to reduction of intracellular calcium concentration. Apart from regulation of vascular tone through vasodilation, nitric oxide also mediates other important vascular homeostatic functions by exerting inhibitory effects on vascular smooth muscle proliferation,⁴³ counteracting leucocyte adhesion to the endothelium^{44,45} and inhibiting platelet aggregation.⁴⁶

The endothelium also mediates hyperpolarisation of the vascular smooth muscle to cause relaxation.^{47,48} Although the identity of the endothelium-derived hyperpolarizing factor remains elusive, its hyperpolarizing mechanism is in general considered to be mediated by calcium-activated potassium channels on vascular smooth muscle.^{49–52} Candidates of endothelium-derived hyperpolarizing factor include epoxyeicosatrienoic acids,^{53,54} potassium ion,⁵⁵ gap junctions,⁵⁶ and hydrogen peroxide.⁵⁷ In human forearm circulation, endothelium-derived hyperpolarizing factor appears to be a cytochrome P-450 derivative, possibly an epoxyeicosatrienoic acid,⁵⁸ and contributes to basal vascular resistance and vasodilation evoked by substance P and bradykinin.⁵⁹ There is a suggestion that endothelium-derived hyperpolarizing factor might play a compensatory role for the loss of nitric-oxide mediation vasodilation in patients with heart failure.^{59,60} Other endothelium-derived vasodilators include prostacyclin and bradykinin. Prostacyclin is produced via the cyclo-oxygenase pathway and acts independently of nitric oxide to cause vasodilation.⁶¹ It also acts synergistically with nitric oxide to inhibit platelet aggregation. Prostacyclin appears to have a limited role in humans in the control of vascular tone. Bradykinin stimulates release of nitric oxide, prostacyclin, and endothelium-derived hyperpolarizing factor.

Regulation of vascular tone by the endothelium is accomplished not only by release of vasodilators, but also by the control of vasoconstrictor tone through release of endothelin⁶² and conversion of angiotensin I to angiotensin II at its surface.⁶³ Endothelin-1, the predominant endothelin isoform in the cardiovascular system, binds to ET_A receptors on vascular smooth muscle cells to cause vasoconstriction.⁶⁴ At lower concentration, however, endothelin-1 causes transient vasodilation in human forearm circulation,⁶⁵ probably due to stimulation of release of nitric oxide and prostacyclin via ET_B receptors located on endothelial cells.⁶⁶

Vascular Smooth Muscle Function

The primary function of the vascular smooth muscle cells is contraction, during which the cells shorten to reduce vessel diameter, alter vascular tone, and regulate blood flow. This contractile phenotype of vascular smooth muscle cells is characterised by expression of genes that encode contractile proteins, ion channels, and other molecules involved in contraction.^{67,68} Excitation-contraction coupling is the process by which cellular signaling pathways modulate activities of ion channels in the smooth muscle sarcolemma, thereby causing alterations in intracellular calcium signaling and other signaling cascades and resulting in contraction or relaxation of vascular smooth muscle cells. The regulation of smooth muscle contraction *in vivo* is primarily by pharmacomechanical and electromechanical activation of the contractile proteins myosin and actin.⁶⁹ Pharmacomechanical coupling refers to activation of contraction by ligands of cell surface receptors without obligatory change in plasma membrane potential. In vascular smooth muscle, the phosphoinositide signaling cascade is the common secondary messenger system utilised by the surface receptors. Electromechanical coupling, on the other hand, involves alterations in plasma membrane potential. Receptor activation may induce an activation of

receptor-operated or voltage-dependent channels and lead to passive influx of calcium down its concentration gradient. Detailed discussion of the molecular mechanisms of smooth muscle contraction is beyond the scope of this chapter. Interested readers are referred to several recently published reviews.^{70–74} The balance between force generation and release is responsible for the maintenance of vascular tone,⁷¹ which can be envisaged as the sum of forces generated in the vessel wall to oppose the increase in vessel diameter. The vascular tone is influenced by local metabolic substances, humoral factors, and activity of the autonomic nervous system. In the smallest arteries and arterioles, contraction of vascular smooth muscle causes large reduction in the vascular lumen and increases peripheral vascular resistance. In large elastic and muscular conduit arteries, the change in vascular tone is accompanied by an increase in elastic modulus, and hence stiffness, of the arteries.

Apart from a contractile phenotype, vascular smooth muscle cells exhibit other phenotypes. This phenotypic diversity plays an important role in normal development, repair of vascular injury, and vascular disease process.^{75,67} Hence, after vascular injury, phenotypic modulation of vascular smooth muscle cells causes upregulation of genes required for their proliferation and production of extracellular matrix and suppression of genes that characterise the contractile phenotype. On the other hand, inappropriate pathological differentiation into other mesenchymal lineages as osteoblastic, chondrocytic, and adipocytic ones may contribute to vessel calcification, altered matrix production, and abnormal lipid accumulation, respectively.^{76–80} Recent studies have focused on the understanding of mechanisms that underlie the physiological control and pathologic alterations of phenotypic switching of vascular smooth muscle cells.^{67,75,81}

Control of Circulation

The regulation of circulation aims to adjust precisely the blood flow in relation to tissue needs and to maintain adequate driving pressure to perfuse the various body tissues. Such control is achieved through local mechanisms, humoral factors, and neural regulation.

Local Control

Auto-regulation refers to the ability to maintain relatively constant blood flow in response to acute changes in perfusion pressure. The coronary, renal, and cerebral circulations exhibit auto-regulation. Two theories have been proposed for this auto-regulatory mechanism. The metabolic theory⁸² suggests that elevated perfusion pressure increases blood flow, and hence oxygen delivery and removal of vasodilators, thereby leading to vasoconstriction and reduction of blood flow and vice versa. The myogenic theory⁸³ proposes that stretching of vascular smooth muscle cells by the elevated perfusion pressure increases their tension, which in turn causes vasoconstriction and reduces the blood flow back to normal. Conversely, less stretching at low pressure leads to smooth muscle relaxation and increased blood flow. The physiological relevance of myogenic constriction lies in its influence on peripheral vascular resistance, provision of vascular tone, and contribution to control of capillary pressure. However, the exact mechanisms that link intraluminal pressure generation to myogenic constriction remain uncertain.⁸⁴

Metabolic mechanisms also contribute to the control of local blood flow. Two theories have likewise been proposed. The vasodilator theory proposes that vasodilator substances are formed and released from tissues when metabolic rate increases or oxygen and other nutrient supplies decrease. Suggested vasodilator substances include adenosine, carbon dioxide, potassium ion, hydrogen ion, lactic acid, histamine, and adenosine phosphate. The nutrient theory suggests that blood vessels dilate naturally when oxygen or other nutrients are deficient. Hence, increased metabolism causes local vasodilation by increased utilisation of oxygen and nutrients, a phenomenon known as active hyperaemia. Reactive hyperaemia is another phenomenon related to local metabolic flow control mechanism. In reactive hyperaemia, brief interruption of arterial blood flow results in transient increase in blood flow that exceeds the baseline, after which the flow returns to baseline level. Both the deprivation of tissue oxygen and accumulation of vasodilating substances probably account for this phenomenon. The duration of reactive hyperaemia depends on the duration of flow cessation and usually lasts long enough to repay the oxygen debt.

Autoregulation and metabolic mechanisms control blood flow by dilation of microvasculature. The consequent increase in blood flow dilates the larger arteries upstream via the mechanism of flow-mediated dilation. The pivotal role of endothelial cells in the transduction of shear stress secondary to increased blood flow and the release of the vasodilators has been alluded to earlier. Flow-mediated dilation has been shown to occur predominantly as a result of local endothelial release of nitric oxide.⁸⁵ The mechanisms of shear stress detection and subsequent signal transduction are unclear, but probably involve opening of calcium-activated potassium channels^{86–88} that hyperpolarises endothelial cells and calcium activation of endothelial nitric oxide synthase.^{85,89} Flow-mediated dilation allows flow to increase with a negligible increase in pressure gradient, thus optimizing energy losses within the circulation.⁹⁰ The phenomenon of flow-mediated dilation as induced by reactive hyperaemia has commonly been used as an assessment of endothelial function *in vivo*. All of the aforementioned mechanisms represent relatively acute responses to regulate local blood flow. Long-term local mechanisms involve changes in tissue vascularity, release of angiogenic factors, and development of collateral circulations.

Humoral Control

Humoral control refers to regulation by hormones or locally produced vasoactive substances that act in an autocrine or a paracrine fashion. These humoral substances act either directly via receptors on vascular smooth muscle cells or indirectly through stimulation of the endothelium to release vasoactive substances.

Circulating catecholamines, noradrenaline and adrenaline, are secreted by the adrenal medulla, which is innervated by pre-ganglionic sympathetic fibres. Sympathetic activation stimulates the release of catecholamines, about 80% being noradrenaline, from the adrenal gland. The adrenal gland and the noradrenergic sympathetic vasoconstrictor fibres provide dual control of circulation by catecholamines. Adrenergic receptors in the blood vessels are α_1 , α_2 , and β_2 receptors. Noradrenaline causes vasoconstriction by acting on α -receptors, while adrenaline causes

vasodilation at physiological concentrations through its β -agonistic effect. At higher concentrations, adrenaline also causes vasoconstriction through activation of α -receptors.

The regulatory role of the renin-angiotensin system in the circulation is well known. The final effector of the system, angiotensin II, mediates its effects classically in an endocrine fashion. In response to decreased renal perfusion pressure or extracellular fluid volume, renin is secreted from the juxta-glomerular apparatus of the kidney and cleaves angiotensinogen, released from the liver, to form angiotensin I. By the action of angiotensin-converting enzyme, which is predominantly expressed on the surface of endothelial cells in the pulmonary circulation, angiotensin I is activated to angiotensin II. Angiotensin II is a potent vasoconstrictor and acts directly by stimulating the angiotensin II type I (AT_1) receptor and indirectly by increasing sympathetic tone and release of vasopressin. Recently, it has become obvious that a local paracrine renin-angiotensin system exists in the vasculature.^{91,92} Vascular production of angiotensin II has been shown to be mediated by the endothelium.⁹³ The tissue renin-angiotensin system has dual effects on vessel function, being mediated through opposing effects of two receptors. Stimulation of AT_1 receptor causes contraction of vascular smooth muscle by directly increasing intracellular calcium and indirectly stimulating synthesis of endothelin-1 and other vasoconstrictors.⁹⁴ Furthermore, promotion of oxidative stress via the AT_1 receptor may possibly reduce nitric oxide bioavailability.^{95,96} On the other hand, stimulation of angiotensin II type 2 receptor appears to mediate vasodilation through activation of the nitric oxide pathway.⁹⁷ The local tissue angiotensin II hence also plays an important role in maintaining vascular homeostasis. Additionally, recent studies have shown that other biologically active aminopeptides of the circulating renin-angiotensin system, such as angiotensins III and IV, may act in the central nervous system to raise blood pressure through the AT_1 receptor.⁹⁸

Three peptides of the natriuretic peptide family, atrial natriuretic peptide, brain natriuretic peptide, and C-type natriuretic peptide, participate in the control of circulation. The atrial natriuretic peptide is primarily produced by the atrial myocardium, while the brain natriuretic peptide is synthesised by the ventricular myocardium. The main stimulus for their release is stretching of the myocardium. Other stimuli include endogenous vasoactive factors, neurotransmitters, pro-inflammatory cytokines, and hormones.^{99,100} The vascular effects of atrial and brain natriuretic peptides are similar. Both reduce sympathetic tone through suppression of sympathetic outflow from the central nervous system, reduction of release of catecholamines from autonomic nerve endings, and probably damping of baroreceptors.^{101,102} The consequence is decreased vascular tone and increased venous capacitance. The atrial and brain natriuretic peptides also inhibit the activities of the renin-angiotensin system, endothelins, cytokines, and vasopressin.^{99,103,104} The renal haemodynamic effects include induction of diuresis, secondary to increased glomerular filtration rate due to vasodilation of afferent renal arterioles and vasoconstriction of the efferent arterioles,¹⁰⁵ and promotion of natriuresis. Despite preload reduction, reflex tachycardia is suppressed as these peptides lower the activation threshold of vagal afferents. C-type natriuretic peptide is a more potent dilator of veins than the other

natriuretic peptides and acts in an autocrine or paracrine fashion.

Adrenomedullin was first isolated from human pheochromocytoma cells, identified by its ability to stimulate cyclic adenosine monophosphate in platelets.¹⁰⁶ It was subsequently found that adrenomedullin is produced in a wide range of cells, including vascular endothelial and smooth muscle cells.^{107,108} Evidence is accumulating that adrenomedullin may function as a novel system in the control of circulation.^{109,110} Infusion of adrenomedullin via the brachial artery in humans has demonstrated dose-dependent vasodilation and increase in blood flow.¹¹¹ Furthermore, the finding of variable blockade of the vasodilating effect of adrenomedullin by inhibition of nitric oxide synthase activity suggests that nitric oxide may be an important mediator for adrenomedullin.^{112–114}

The endothelium-derived vasoactive substances and their role in the control of vascular tone and homeostasis were discussed earlier. While prostaglandins are produced by most tissues, prostacyclin (prostaglandin I_2) is the main prostanoid produced by the endothelium of blood vessels. Prostacyclin is a potent vasodilator and an inhibitor of platelet aggregation. Nonetheless, it appears to have a limited role in humans in the control of basal vascular tone. The balance of actions between two antagonistic prostanoids, prostacyclin and thromboxane A_2 , has been the recent focus of attention in the light of reported adverse effects of selective inhibition of cyclooxygenase-2.^{115,116} Prostaglandins and thromboxane are eicosanoids generated by metabolism of arachidonic acid, a major unsaturated fatty acid present in the phospholipids of cell membranes. Arachidonate is released from the membrane phospholipids by phospholipase A_2 due to a variety of mechanical and neurohumoral stimuli. Arachidonate is then converted to prostaglandin H_2 by prostaglandin H synthase, also known as cyclooxygenase. Specific synthases then produce the biologically active end products of this metabolic pathway, namely prostaglandin E_1 , prostaglandin $F_2\alpha$, prostacyclin, and thromboxane A_2 . The endothelial cells produce predominantly prostacyclin and lesser amounts of prostaglandin E_1 , also a vasodilator, and prostaglandin $F_2\alpha$, a vasoconstrictor.¹¹⁷ Thromboxane A_2 , although predominately generated by platelets, is also synthesised by the endothelium¹¹⁸ and induces vasoconstriction and platelet aggregation. Cyclooxygenase exists in two isoforms: cyclooxygenase-1 and cyclooxygenase-2.^{119,120} Whether endothelial production of prostacyclin depends on cyclooxygenase-1 or -2 activity, however, remains debatable.^{116,121,122} Under normal physiological conditions, eicosanoids, primarily prostacyclin, produced by the cyclooxygenase pathway induce vasorelaxation.¹²⁰ Furthermore, the cyclooxygenase-dependent vasodilators can compensate for the deficiency of other vasorelaxants.¹²³ By way of the lipoxygenase pathway, leucotrienes are produced from arachidonic acid. Leucotrienes C_4 , D_4 , and E_4 cause arteriolar constriction, while leucotrienes B_4 and C_4 induce pulmonary vasoconstriction by activating cyclooxygenase to produce thromboxane A_2 .¹¹⁷

Several other endogenous substances affect the systemic circulation. Vasopressin, produced in the supraoptic and paraventricular nuclei of the hypothalamus, is probably the most potent known endogenous constrictor. It is released in quantities sufficient to exert a pressor effect when volume

depletion is significant. It has, however, little role in normal vascular control.^{124,125} Serotonin exists in large amount in the enterochromaffin cells of the gastrointestinal tract. Although serotonin exerts vasoconstrictor and vasodilator effects, depending on vasculature, its function in the regulation of circulation is unknown. Kinins are among the most potent endogenous vasodilators. Examples of kinins include bradykinins and kallidin, which are formed from the action of kallikrein on the α_2 -globulin kininogen. Kinins cause vasodilation and increase capillary permeability. Bradykinin is believed to play a role in the control of blood flow in the skin, gastrointestinal glands, and salivary glands. Histamine is located in mast cells and basophils. Histamine is released from these cells upon stimulation by injury, inflammation, or allergic reaction to induce vasodilation and increase capillary permeability.

Neural Control

Neural control of the systemic circulation involves feedback mechanisms that operate in both the short and long term through the autonomic, primarily the sympathetic, nervous system.¹²⁶ Short-term changes in sympathetic activity are triggered either by reflex mechanisms involving peripheral receptors or by a centrally generated response. Long-term changes, on the other hand, are evoked through modulation of the sympathetic nervous system by other humoral factors and possibly by central mechanisms involving the hypothalamus.

Peripheral receptors that constitute the afferent limb of the reflex are arterial baroreceptors, arterial chemoreceptors, and cardiac stretch receptors. Arterial baroreceptors are located in the walls of the carotid sinus and aortic arch. Afferent fibres run in the glossopharyngeal and vagal nerves and terminate within the nucleus tractus solitarius. The nucleus tractus solitarius neurons then excite neurons within the caudal and intermediate parts of the ventrolateral medulla to cause inhibition of the sympathoexcitatory neurons in the rostral ventrolateral medulla.¹²⁷ Hence, stretching of arterial baroreceptors increases afferent input and results in reflex slowing of heart rate, decrease in cardiac contractility, and vasodilation, thereby providing a negative feedback mechanism for homeostasis of arterial pressure.¹²⁸

Peripheral chemoreceptors are located in the carotid and aortic bodies, being stimulated primarily by decreased arterial partial pressure of oxygen. Their afferent fibres also run in the glossopharyngeal and vagus nerves. Activation of peripheral chemoreceptor results in hyperventilation and sympathetically mediated vasoconstriction of vascular beds, with the exception of those of the heart and brain.¹²⁹ Hence, oxygen conservation is attempted by increasing oxygen uptake and reducing tissue oxygen consumption. These chemoreflexes are nonetheless subjected to negative feedback interaction, with inhibition of the chemoreflex-mediated sympathetic activation through stimulation of baroreceptors and thoracic afferents.¹³⁰

Atrial receptors are located in the walls of the right and left atriums and in pulmonary venous and cavoatrial junctions.^{131,132} Two types of atrial receptors are described based on their discharge pattern in relation to atrial pressure waves. Type A receptors signal atrial contraction and hence respond to increase in central venous pressure. These receptors send impulses via myelinated fibres in the vagus nerve, while the efferent portion consists of sympathetic

activation. The tachycardia due to stimulation of sinoatrial node caused by atrial stretch is termed the Bainbridge reflex. Type B baroreceptors are stretch receptors stimulated by volume distention of the atriums and fire during ventricular systole. The afferents are via unmyelinated vagal fibres. Atrial distention decreases sympathetic activity. Receptors which respond to stretch and contractility are also present in the ventricles. The receptors provide afferent input to the medulla via unmyelinated C-fibres.¹³³ Stimulation of these fibres decreases sympathetic tone and causes bradycardia and vasodilation. Stretching of the atrial and ventricular myocardium also leads to the release of natriuretic peptides, as discussed earlier.

Apart from the reflex-triggered short-term control of circulation, the central pathways responsible for the central command responses, such as those occurring at the onset of exercise or evoked by a threatening stimulus, are increasingly understood.¹²⁶ The rostral ventrolateral medulla is traditionally regarded as the vasomotor centre that controls circulation via the autonomic, primarily sympathetic, nervous system.¹³⁴ Nonetheless, accumulating evidence suggests that the dorsomedial hypothalamic nucleus may be a critical region responsible for the integration of autonomic, non-autonomic, and cardiovascular components of the central command responses.¹³⁵ Indeed, recent data suggests that groups of neurons in the hypothalamus can project to synapse directly with sympathetic pre-ganglionic fibres in the spinal cord, implying that the medullary vasomotor centre is perhaps not the only region that directly controls sympathetic outflow.¹³⁶

The autonomic nervous system represents the efferent component of the neural control of the circulation. Up to three types of fibres may innervate blood vessels: sympathetic vasoconstrictor fibres, sympathetic vasodilator fibres, and parasympathetic vasodilator fibres. As the size of vessel decreases, the density of autonomic innervation increases. The small arteries and arterioles are therefore the most richly innervated arteries.

Sympathetic vasoconstrictor fibres release noradrenaline upon nerve stimulation and constitute the most important components in the neural control of circulation. Postsynaptically, the α_1 -adrenoceptor is the predominant receptor mediating vasoconstriction. Although noradrenaline is the principal neurotransmitter in the sympathetic nervous system, it has been observed to co-exist with adenosine triphosphate and neuropeptide Y in sympathetic neurons.^{137,138} Co-transmission refers to the concept of storage and release of more than one type of neurotransmitter,¹³⁹ which is now recognised as the norm of most neurons. Hence, in most blood vessels, adenosine triphosphate and noradrenaline act synergistically to cause vasoconstriction by acting on the post-synaptic P_2 purinoreceptors and α_1 -adrenoceptors, respectively. While neuropeptide Y has little direct action in most vessels, it appears to have an enhancing effect on the post-synaptic activity of adenosine triphosphate and noradrenaline and to act presynaptically to inhibit release of these transmitters.¹⁴⁰ Sympathetic vasoconstriction of arterioles increases vascular resistance, while constriction of capacitance vessels alters the circulating blood volume. In larger arteries, contraction of vascular smooth muscle in response to sympathetic activation causes less significant change in arterial caliber but alters vascular tone and hence arterial stiffness.

Sympathetic vasodilator fibres are scarce and are not tonically active. Evidence suggests that sympathetic vasodilator fibres regulate skeletal vascular tone in many animal species. Both cholinergic¹⁴¹ and nitric oxide-dependent^{142,143} mechanisms contribute to the vasodilator effect. Parasympathetic vasodilator fibres are found in blood vessels of the salivary gland, cerebral arteries, and coronary arteries. The vasodilator effect is mediated via release of acetylcholine with hyperpolarisation of the vascular smooth muscle.

Long-term neural regulation of the circulation is modulated by humoral and other factors. Angiotensin II is an important facilitator of sympathetic transmission. It may enhance neurotransmitter release at sympathetic nerve terminals, sympathetic transmission through sympathetic ganglia,¹⁴⁴ and perhaps central activation of sympathetic nervous activity.¹⁴⁵ Evidence is also accumulating that nitric oxide interacts with the autonomic nervous system at both central and peripheral levels.¹⁴⁶ Centrally, nitric oxide decreases sympathetic vasoconstrictor outflow. Peripherally, augmented vasoconstriction to nitric oxide synthase inhibition has been demonstrated in denervated forearm in humans.¹⁴⁷ Interaction between nitric oxide and cholinergic vasodilator fibres is also evidenced by significant pressor response to nitric oxide synthase inhibition with cholinergic blockade.¹⁴⁸ Finally, accumulating evidence suggests that the hypothalamic paraventricular nucleus in the central pathways may mediate sustained increases in sympathetic nerve secondary to a variety of stimuli.¹²⁷ It has therefore been hypothesised that stress, anxiety, or pathological conditions such as heart failure may exert long-term influence on neural control of circulation through tonic activation of sympathoexcitatory neurons located in paraventricular nuclei of the hypothalamus.¹²⁶

MODELING OF SYSTEMIC CIRCULATION

Models

From the mechanical perspective, the systemic arterial system can be envisaged as a network of elastic tubes that receive pulsatile blood flow from left ventricular ejection and transmit it distally as a steady stream into capillaries. Hence, apart from acting as a low-resistance conduit, the systemic arterial tree functions as a cushion to smooth out pressure and flow pulsations generated by cycles of left ventricular contraction. While the success of the conduit function depends primarily on a low peripheral vascular resistance, the efficiency of cushioning function depends on the elastic properties, described in terms of stiffness, of the arterial system. Importantly, stiffness of the arterial system is related to vascular impedance, the opposition to blood flow taken to represent the afterload presented by the systemic arterial circulation to the left ventricle.

Modeling of the arterial circulation has contributed significantly to the understanding of the behaviour of the arterial system and the effects of arterial load on the systemic ventricle. The lumped model of arterial circulation, commonly termed *Windkessel* model, was first described in the eighteenth century. In his book entitled *Haemastatics*, Hales drew an analogy between the arterial system and an air-filled dome of the fire engine compression chamber (*Windkessel*)¹⁴⁹ (Fig. 6-1). The dome represents the cushioning function of the arteries, which buffers intermittent spurts of water from the pump. The rigid fire hose represents the

Figure 6-1 Windkessel model of the arterial system. The Windkessel buffers spurts of water from the pump, while the fire hose functions as a low resistance conduit. (Reproduced with permission from O'Rourke MF: Arterial function in health and disease. Edinburgh: Churchill Livingstone, 1982.)

conduit function, while the nozzle represents the peripheral resistance. As an analogy, blood ejected from the left ventricle distends the large elastic arteries during systole, while elastic recoil of the arteries during diastole propels blood to perfuse the peripheral resistance vessels. This cushioning function smooths out the pulsatile blood flow and protects the peripheral vascular beds from exposure to large pressure fluctuations. The electrical analogues of the systemic arterial system are shown in Figure 6-2. The two-element electrical analogue of the Windkessel model comprises a capacitor, which represents the arterial compliance, and a resistor, the total peripheral resistance. To better characterise the arterial system, a modified Windkessel model has been proposed¹⁵⁰ to take into account the input impedance of the proximal aorta by addition of a

Figure 6-2 Electrical analogues of the systemic arterial system. A, Classic two-element Windkessel model with arterial compliance being represented by a capacitor (C) and the peripheral resistance by a resistor (R). B, A modified Windkessel model with addition of a proximal resistor (Z_0) to represent characteristic impedance of the proximal aorta. C, A four-element Windkessel model with incorporation of an inductance element (L).

resistor proximal to the two-element capacitance-resistance model. A four-element Windkessel model, with addition of an inertial term, has further been shown to be superior to the three-element Windkessel as a lump model of the entire systemic tree.¹⁵¹ Inertance is due to mass of the fluid and physiologically; it can be regarded as the inertial effect secondary to simultaneous acceleration of the blood mass within the vessel.

The Windkessel model, albeit simple and qualitative, emphasises the elasticity of the large arteries and resistance offered by the small peripheral arteries. Nonetheless, this model has intrinsic shortcomings: limitation of vessel elasticity to one site, lack of a finite velocity of propagation of the pulse wave, and overlooking of the significance of wave reflection. In this model, the pressure generated by contraction of the systemic ventricle is assumed to be transmitted instantaneously throughout the windkessel, the pressure pulse is assumed to subside before the next cardiac cycle, and there is a single systolic and a single diastolic blood pressure throughout the major arteries. However, the fact that the cushioning and conduit functions of the arterial tree are combined results in two phenomena: (1) traveling of pulse wave at a finite speed along the arterial wall, and (2) wave reflection at arterial terminations and other discontinuities. A more realistic model proposed is a distensible tube with one end receiving pulsatile ejection of blood from the left ventricle and with the other end representing the peripheral resistance.¹⁵² The pressure wave at any point along the tube is regarded as a result of the incident and reflected waves. The velocity at which the pulse travels depends on the elasticity of the tube and has implications on the timing of arrival of the reflected wave. When the tube is distensible, the wave velocity is slow and the reflected wave returns late in diastole. By contrast, when the tube is stiffened, the pulse velocity is increased and the reflected wave merges with the systolic part of the incident wave, causing a higher pressure in systole and a lower pressure in diastole. It is conceivable, therefore, that stiffness is an important mechanical property of the arterial tree and contributes to left ventricular afterload.

Arterial Impedance as Ventricular Afterload

Ventricular afterload can be conceptualised as all those external factors that oppose ventricular ejection and contribute to myocardial wall stress during systole. The hydraulic load of the systemic arterial system has therefore been taken to represent the afterload presented to the systemic ventricle.^{153,154} The total arterial hydraulic load comprises three components: resistance, stiffness, and wave reflection, all of which can be obtained from impedance spectra based on analysis in the frequency domain.¹⁵⁵

Vascular Resistance

Vascular resistance is commonly used in the clinical setting as an index of systemic ventricular afterload. The electrical analogue for vascular resistance is described by Ohm's law, which applies to direct electric current circuit. For a steady flow state, the vascular resistance is derived by dividing pressure gradient by volume flow. As the systemic venous pressure is very small when compared with the mean aortic pressure, the systemic arterial resistance can be approximated as mean aortic pressure divided by cardiac output. Nonetheless, as arterial blood flow is pulsatile in nature,

the use of vascular resistance alone to describe afterload is deemed inadequate.

Vascular Impedance

For pulsatile flow, the corresponding pressure-flow relationship is vascular impedance. This is analogous to the voltage-current relationship of an alternating current electric circuit. To analyse the mathematical relationship between pressure and flow waves, Fourier analysis is used to decompose these complex non-sinusoidal waves into a set of sinusoidal waves with harmonic frequencies that are integral multiples of the fundamental wave frequency (Fig. 6-3). Each of the sinusoidal components is described in terms of frequency, amplitude, and phase angle.

In applying Fourier analysis to the circulatory system, two prerequisites have to be fulfilled: periodicity and linearity. Regularity of the heartbeat can generally be regarded as a type of steady-state oscillation.¹⁵⁶ For a linear system, when the system is driven by a pure sine wave of a certain frequency, no pressure or flow components of another frequency should be generated. By contrast, there will be interactions between harmonic components and creation of additional frequency components in a non-linear system. Hence, strictly speaking, the harmonic terms of the pressure should be related exclusively to the corresponding harmonic terms of flow if the circulatory system is linear. While non-linearities of the circulatory system do exist, their magnitude is small.¹⁵⁷ Importantly, the arterial system has been shown to be linear for normal physiological oscillations.^{156,158}

Vascular input impedance is defined as the ratio of pulsatile pressure to pulsatile flow. The aortic input impedance is particularly relevant as it characterises the properties of the entire systemic arterial circulation and represents the hydraulic load presented by the systemic circulation to the left ventricle.^{153,154} To obtain the aortic input impedance spectrum, the ascending aortic flow is usually measured by an electromagnetic flow catheter, while the pressure is measured by a micromanometer mounted onto the catheter. Noninvasive determination of aortic input impedance involves the use of Doppler echocardiography to measure flow and tonometry to obtain a carotid, subclavian, or synthesised aortic pressure waveform, the latter based on the radial arterial waveform.

Figure 6-3 Decomposition of complex non-sinusoidal pressure and flow waves into a set of sinusoidal waves with harmonic frequencies at multiples of the frequency of heart rate (first or fundamental frequency) using Fourier analysis.

An example of the human aortic input impedance spectra is shown in Figure 6-4. The vascular impedance modulus at different harmonics is the ratio of pressure amplitude to flow amplitude. For a heart rate of 60 beats/min, the fundamental frequency is 1 Hz, the second harmonic is 2 Hz, and so forth. Beyond the 10th harmonic, the magnitudes are usually small and negligible. At zero frequency, impedance is equivalent to resistance in the steady-flow state. The phase difference is the delay in phase angle between the pressure and flow harmonics, which is analogous to time delay in the time domain. When a particular pressure harmonic leads the flow harmonic, the phase angle is positive. Conversely, when the pressure harmonic lags behind the corresponding flow harmonic, the phase is negative. The aortic input impedance spectrum is characterised by a steep decrease in the magnitude of input impedance from its value at zero frequency (resistance), followed by fluctuations with maxima and minima. The fluctuations of the impedance modulus are related to peripheral wave reflection as discussed in the following section. The average of the relatively stable high-frequency components of the impedance moduli provides an approximation of characteristic impedance.

Characteristic impedance is the ratio of pulsatile pressure to pulsatile flow at a site where pressure and flow waves are not influenced by wave reflection. The concept of characteristic impedance is important as it is principally

Figure 6-4 Aortic input impedance spectra obtained in normal adults. (Reproduced with permission from Nichols WW, Conti CR, Walker WE, Milnor WR: Input impedance of the systemic circulation in man. *Circ Res* 1977;40:451-458.)

determined by and related directly to stiffness of the major arteries distal to the site of measurement. Hence, it represents the pulsatile component of the hydraulic workload presented to the left ventricle when it is measured at the ascending aorta. As wave reflection is always present, characteristic impedance cannot be measured directly. It is usually estimated by averaging impedance moduli over a frequency range where fluctuations due to wave reflection above characteristic impedance are expected to cancel out those below.¹⁵⁹ Hence, characteristic impedance has been estimated as the average value of modulus between 2 and 12 Hz,¹⁶⁰ above 2 Hz,¹⁶¹ or above the frequency of the first minimum.¹⁵² In the time domain, the characteristic impedance can be estimated by relating the initial upstroke of the pressure wave to the upstroke of the simultaneously recorded flow wave,¹⁶² as the effects of wave reflection are minimal with the first 20 msec of the wave.

Wave Reflection

As the velocities of pressure and flow waves transmitted in the arteries are of the order of metres per second, it is obvious that the waves have sufficient time to travel to the periphery and be reflected back before the next cardiac cycle. The existence of wave reflections is supported by several observations. A secondary pressure wave is usually obvious in arterial pressure pulse when flow is in fact decreasing. Furthermore, such secondary pressure waves show different patterns in different arteries.^{163,164} Wave reflection also accounts for the observed amplification of the pulse between central and peripheral arteries.¹⁵²

As a result of non-uniformities of geometric and elastic properties along the arterial tree and impedance mismatch at the arterial termination, wave reflection sites can exist throughout the arterial system. There is no universal agreement on the reflecting sites, with possible ones including branching points in major arteries,^{165,166} areas of alterations in arterial stiffness,¹⁶⁷ and high-resistance arterioles.¹⁵² Nonetheless, the terminations at which low-resistance conduit arteries terminate in high-resistance arterioles are usually regarded as the principal sites for reflection. Wave reflection in the ascending aorta hence represents the result of reflections at multiple peripheral sites of the body.

The pressure and flow waves measured at any site in the arterial system can therefore be considered as a summation of a forward or incident wave and a reflected wave. Wave reflection exerts opposite effects on pressure and flow. Reflected pressure wave increases the amplitude of the incident pressure wave, while reflected flow wave decreases the amplitude of the incident flow wave. In most experimental animals and in young human subjects who have elastic arteries, wave reflection returns to the ascending aorta from the periphery after ventricular ejection.¹⁵² Such timing is desirable, as the reflected pressure wave augments early diastolic blood pressure, thereby boosting the perfusion pressure of the coronary arteries without increasing left ventricular afterload.

Alteration of arterial stiffness has profound effects on wave reflection. Stiffening of systemic arteries due to aging or disease processes increases pulse wave velocity and causes earlier return of the reflected wave to augment aortic blood pressure in late systole rather than in diastole, the implications of which will be discussed in the section on ventriculo-arterial interaction.

MEASURES OF ARTERIAL FUNCTION

Arterial Stiffness

Arterial stiffness describes the rigidity of the arterial wall. In the last decade, there has been increasing interest in the potential role of arterial stiffening in the development of cardiovascular disease in adults. Arterial stiffness is primarily determined by structural components of the arterial wall, elastin and collagen in particular, vascular smooth muscle tone, and transmural distending pressure.¹⁶⁸ Increasing evidence suggests a role for endothelium in the regulation of arterial stiffness through the influence of smooth muscle tone by release of vasoactive mediators. Indeed, the influence of basal nitric oxide production¹⁶⁹ and endothelin-1¹⁷⁰ on stiffness of the common iliac artery in an ovine model have recently been shown. Additionally, it has been shown that atrial natriuretic peptide and, to a lesser extent, brain natriuretic peptide can modify iliac artery stiffness in this animal model.¹⁷¹

The significance of arterial stiffness, as alluded to earlier, owes to its direct relationship with characteristic impedance, hence the pulsatile component of the arterial afterload, and its effect on the timing of return of the reflected waves from peripheral sites. On the one hand, atherosclerotic changes with thickening, fibrosis, and fragmentation and loss of elastin fibres can stiffen the arterial wall by causing structural alterations¹⁷²; on the other, arterial stiffening may predispose the intima to atherosclerosis due to injury sustained from increased pulsatile pressure.¹⁷³ Indeed, aortic stiffness has been positively associated with the extent of coronary arterial plaque load in elderly subjects undergoing elective coronary angiography.¹⁷⁴

The contention that arterial stiffness is a marker of vascular disease and a risk factor for cardiovascular morbidity and mortality in adults is gaining support, and the role of arterial stiffness in the development of cardiovascular disease is increasingly emphasised.¹⁷⁵ The association in adults of increased arterial stiffness and various pathophysiological conditions, which are themselves also associated with increased cardiovascular risk, has been extensively reviewed.^{175–178} Studies have also shown that arterial stiffness is associated with end-organ alterations including left ventricular hypertrophy and arterial intima-media thickening in adults independent of systemic blood pressure.¹⁷⁹ Importantly, stiffness of central arteries, as assessed by aortic pulse wave velocity and carotid distensibility, has been shown to have independent predictive value for cardiovascular events in the general adult population,^{180,181} in the elderly,¹⁸² in adults with hypertension,^{183–185} in end-stage renal failure,^{186–189} and with impaired glucose tolerance.¹⁹⁰

While central arterial stiffness has been the focus of most of the adult studies, the contribution of stiffness of the smaller peripheral arteries to total vascular impedance should not be ignored. Structural remodeling occurs also in smaller arteries and branching points. The changes in mechanical properties of conduit and resistive arteries influence wave reflections and contribute to augmentation of late systolic blood pressure in the aortic root.¹⁹¹ Hence, carotid augmentation index has also been shown to have independent predictive value for cardiovascular events in adults with hypertension,¹⁹² and end-stage renal failure¹⁹³ and in those undergoing percutaneous coronary interventions.¹⁹⁴ Associations between increased small artery stiffness, as assessed by pulse contour analysis, and aging,

hypertension, smoking, diabetes, and cardiovascular events have also been reported.^{195,196}

The increasing application of non-invasive methods to determine systemic arterial stiffness in the clinical and research arenas has significantly increased the understanding of its pathophysiological significance. With adoption of these non-invasive methodologies for use in children and adolescents,^{197,198} the phenomenon and significance of arterial stiffening in the young is also beginning to unveil.

Measurement of Arterial Stiffness in Vivo

Non-invasive methods for determination of local, regional, and systemic arterial stiffness and quantification of wave reflections in vivo are available. For meaningful interpretation of these indices, their fundamental limitations have to be taken into account. First, the relationship between pressure and arterial diameter is nonlinear due to progressive recruitment of the stiffer collagen as transmural pressure increases. Arterial stiffness should therefore be quantified at a given level of pressure as the tangent to the pressure-diameter curve.¹⁵² Importantly, comparison of arterial stiffness among different populations should take into account the potential confounding influence of the distending pressure. Second, modulation of smooth muscle tone by sympathetic nervous activity, hormones, or endothelium-derived vasoactive substances as mentioned above can alter arterial stiffness. Finally, spontaneous vasomotor changes in the muscular arteries can alter arterial diameter and stiffness.¹⁹⁹

Local Arterial Stiffness

Local arterial stiffness is obtained by relating pressure changes to arterial diameter or cross sectional area changes at the site of interest. Arterial stiffness can be expressed as compliance, distensibility, Person's elastic modulus, Young's modulus, and stiffness index^{175,200,201} (Table 6-1). The elastic property of the artery as a hollow, circular structure is described by distensibility, compliance, Peterson's elastic modulus, and stiffness index. The elastic property of the arterial wall, on the other hand, is estimated by Young's elastic modulus that takes into account the wall thickness, which is usually estimated by the intima-media thickness. Assumption of homogeneity of the non-homogeneous arterial wall, however, underestimates Young's elastic modulus. Among the various indices of local arterial stiffness, the stiffness index is considered relatively independent of systemic blood pressure.²⁰²

For superficial arteries such as the brachial, femoral, and carotid arteries, the diameter and diameter change from end-diastole to systole can be assessed by ultrasound and echo-tracking techniques. Two-dimensional ultrasound assessment is, however, limited by the precision of measurements. In contrast, echo-tracking devices process radio-frequency signals to track the displacement of the anterior and posterior arterial walls with a high precision.^{203,204} The difference between displacements, which reflects changes in arterial diameter as a function of time, can then be displayed (Fig. 6-5). The precision in determining the change in diameter has been estimated to be as low as 1 μm for echo-tracking devices and about 150 μm for video-image analysis of ultrasound images.^{175,203,205} Furthermore, the intima-media thickness can be estimated from the radio-frequency signals, which enable calculation of Young's elastic modulus. An additional advantage of echo-tracking

TABLE 6-1

INDICES OF LOCAL ARTERIAL STIFFNESS

Term	Definition	FORMULA	
		in Terms of Change in Vessel Diameter	in Terms of Change in Cross Sectional Area of Vessel Lumen
Compliance	Absolute change in diameter or area during systole for a given pressure change	$\Delta D/\Delta P$	$\Delta A/\Delta P$
Distensibility	Relative change in diameter or area during systole for a given pressure change	$\Delta D/(D \cdot \Delta P)$	$\Delta A/(A \cdot \Delta P)$
Peterson's elastic modulus	Inverse of distensibility, i.e., the pressure change required for a given relative change in diameter or area	$\Delta P \cdot D/\Delta D$	$\Delta P \cdot A/\Delta A$
Stiffness index (β)	Ratio of ln (systolic/diastolic pressure) to relative change to vessel diameter	$\ln (P_s/P_d)/(\Delta D/D)$	
Young's modulus or incremental elastic modulus	Elastic modulus per unit wall thickness or area; provides information on intrinsic elastic properties of the arterial wall	$\Delta P \cdot D/\Delta D \cdot h$	$[3(1+A/WCSA)]/ \text{cross sectional distensibility}$

A, diastolic cross sectional area; ΔA , difference in systolic and diastolic cross sectional area; D, diastolic diameter; ΔD , difference in systolic and diastolic diameter; h, wall thickness; ΔP , pulse pressure; P_d , diastolic blood pressure; P_s , systolic blood pressure; WCSA, wall cross sectional area = $\pi(D/2 + \text{intima-media thickness})^2 - \pi(D/2)^2$.

devices is that a pressure-diameter curve can be plotted for determination of arterial stiffness at any given blood pressure.^{168,206} For deeper arteries such as the aorta, cine magnetic resonance imaging²⁰⁷ and transoesophageal echocardiography with acoustic quantification²⁰⁸ have been used to determine diameter change during the cardiac cycle.

Ideally, the local pressure should be measured at the site of diameter measurements. Applanation tonometry allows noninvasive recording of the arterial pressure waveform in the carotid and peripheral conduit arteries.²⁰⁹ Gentle compression of the superficial artery against the underlying bone by the pen-like tonometer allows its equalisation with the arterial circumferential pressure. The recorded pressure waveform, almost identical to that obtained intra-arterially, can then be calibrated against the cuff mean and diastolic blood pressures of the brachial artery.^{210,211} Derivation of central aortic waveform from radial arterial tonometry has also been made possible by application of a transfer function, which has been validated in adults²¹²⁻²¹⁴ but not in children. Although cuff brachial artery pulse pressure has

Figure 6-5 Echo-tracking technique. The upper panel shows the radio-frequency signal, while the lower panel shows displacement of the anterior (Ant.) and posterior (Pos.) walls of the artery as a function of time, and the total distention (Dist.) that reflects the change of arterial diameter. (Reproduced with permission from Reneman RS, Hoeks APC: Non-invasive assessment of artery wall properties in humans—methods and interpretation. *J Vasc Invest* 1996;2:53–64.)

commonly been used for the calculation of local arterial stiffness indices, amplification of pressure pulse along the arterial tree constitutes a potential source of error.

Regional Arterial Stiffness

Arterial stiffness of an arterial segment, or regional stiffness, is assessed by measuring the pulse wave velocity over the segment of interest. Pulse wave velocity is the speed at which the pressure or flow wave is transmitted along the

arterial segment. It is related to Young's elastic modulus (E) by the Moens-Korteweg equation: $PWV = \sqrt{Eh/2\rho r}$, where PWV is pulse wave velocity, h is wall thickness of vessel, r is inside radius of vessel and ρ is density of blood.¹⁵² The Bramwell and Hill²¹⁵ (1922) equation relates pulse wave velocity to arterial distensibility: $PWV = \sqrt{(\Delta P \cdot V)/\Delta V \rho} = \sqrt{1/\rho D}$, where P is pressure, V is volume, $\Delta P \cdot V/\Delta V$ represents volume elasticity, and D is volume distensibility of the arterial segment. Furthermore, pulse wave velocity is directly related to characteristic impedance (Z_c) by the formula¹⁶⁶ $Z_c = PWV \cdot \rho$. Pulse wave velocity is hence related directly to arterial elasticity and characteristic impedance and inversely to arterial distensibility. By providing an average stiffness of the arterial segment of interest, pulse wave velocity may provide a better reflection of the general vascular health. As aforementioned, the value of aortic pulse wave velocity as a risk for cardiovascular morbidity and mortality in adults is increasingly recognised.¹⁷⁵

Pulse wave velocity is determined by dividing the distance of pulse travel by the transit time. As the pressure pulse and flow pulse propagate at the same velocity, the arterial pulse may be registered using pressure-sensitive transducers,²¹⁶ oscillometric devices,²¹⁷ applanation tonometry,²¹⁸ and Doppler ultrasound.^{219,220} Furthermore, the pulse wave can be detected using magnetic resonance imaging,^{221,222} which also allows accurate determination of path length and measurements to be made from relatively inaccessible arteries. Recently, determination of pulse wave velocity based on the principle of photoplethysmography²²³ has also been validated.²²⁴ By contrast to the assessment of local arterial stiffness, measurement of pulse wave velocity does not require accurate measurement of the pressure in the arterial segment of interest.

Transit time is measured as the time delay between the feet of the proximal and distal pulse waves (Fig. 6-6). The time delay can be measured by simultaneously recording the pulse waves at two sites of the arterial segment. Alternatively, the time intervals between the R-wave of the electrocardiogram and the foot of the pulse wave at the two sites may be recorded consecutively, and the transit time calculated as the difference between the two. The foot of the pulse wave is used to locate the wave front as it is relatively unaffected by wave reflections.

Figure 6-6 Determination of pulse transit time. The foot of the pulse wave is used to locate the wavefront as it is relatively unaffected by wave reflections. The time delay can be measured by simultaneously recording pulse waves at two sites of the arterial segment (left). Alternatively, the time intervals between the R-wave of the electrocardiogram and the foot of the pulse wave at two sites may be recorded consecutively, and the transit time calculated as the difference between the two (right).

unaffected by wave reflections. The most consistent method for determination of the foot of the pulse wave has been shown to be either the point at which its second derivative is maximal or the point formed by intersection of a line tangential to the initial systolic upstroke of the waveform and a horizontal line through the minimum point.²²⁵

The distance can be estimated by direct superficial measurement between the centres of the two pressure transducers or other devices in case of relatively straight segments like the brachioradial arterial segment. If arterial segments are not straight, measurement of the distance may be a source of error. Furthermore, in two sites where pulse waves propagate in opposite directions, as in the determination of carotid-femoral pulse wave velocity, the method of measuring distance varies. Some investigators recommend using the total distance between the carotid and femoral sites of measurement, while others subtract the carotid-sternal notch distance from the total distance, or subtract the carotid-sternal notch distance from the femoral-sternal notch distance.^{175,226,227} Despite the limitations of the need to estimate distance by superficial measurement, pulse wave velocity is probably the most widely used technique for assessment of arterial stiffness.

Systemic Arterial Stiffness

Pulse contour analysis has been used to assess systemic or whole-body arterial stiffness non-invasively.^{228–230} One of the methods, based on the electrical analogue of a modified *Windkessel* model with proximal and distal capacitance, inductance, and resistance parameters, concentrates on analysis of the diastolic pressure decay of the radial pulse contour. An algorithm is used to determine the best set of values for matching the diastolic portion of the pulse contour to a multi-exponential waveform equation. Based on these values, the capacitive compliance of the proximal major arteries and the oscillatory compliance of the distal small arteries are estimated. However, the biologic relevance of the lumped proximal and distal compliance derived from a model construct based on assumptions remains to be defined. Nonetheless, these parameters have been shown to change with aging and in diseases associated with increased cardiovascular events,^{228,229} although evidence for their predictive value for the occurrence of such events is lacking.

The area method, based on a two-element *Windkessel* model, has also been used to determine systemic arterial compliance using the formula $\text{compliance} = A_d / [TVR \times (P_{es} - P_d)]$, where A_d is area under the diastolic portion of the arterial pressure wave from end-systole to end-diastole, TVR is total vascular resistance, P_{es} is end-systolic pressure, and P_d is end-diastolic pressure.^{231,232} The pressure and pressure waveform can be obtained by applanation tonometry over the right common carotid artery, while total vascular resistance is calculated as mean blood

pressure divided by mean aortic blood flow, the latter obtained by a velocimeter positioned at the suprasternal notch. The area method nonetheless shares similar limitations.

Wave Reflection Indices

Arterial stiffening increases pulse wave velocity and shortens the time for the pulse wave to return from the periphery. Early arrival of the reflected waves augments systolic blood pressure in stiff arteries. The effects of wave reflection can be quantified by determination of this pressure wave augmentation.^{166,233} The augmentation index is defined as the ratio of difference between systolic peak and inflection point to pulse pressure (Fig. 6-7). The inflection point corresponds to the time when peak blood flow occurs in the artery. In adolescents and young adults with elastic arteries, the augmentation index is negative, as late return of reflected waves during diastole causes the peak systolic pressure to precede an inflection point. By contrast, in middle-aged and older individuals, the peak systolic pressure occurs in late systole after an inflection point and the augmentation index becomes increasingly positive with age. The aortic augmentation index is hence negative in adolescents and reaches to about 50% of pulse pressure at 80 years.¹⁵² As height is related to reflection sites, the augmentation index is inversely related to height²³⁴ and is paradoxically greater in infants and young children than in adolescents due to early return of reflected wave with a short body length. Rather than a direct measurement of arterial stiffness, augmentation index is a manifestation of arterial stiffness. It is also important to recognise that apart from arterial stiffness, the amplitude of reflected wave, reflectance point, heart rate, and ventricular contractility are all important determinants of augmentation index.

To determine the aortic augmentation index non-invasively, the central aortic waveform can be estimated from the common carotid artery waveform using applanation tonometry, although this is technically demanding. Alternatively, the aortic waveform can be reconstructed using a transfer function from the radial waveform, which is easier to obtain.^{212–214} The radial-to-aortic transfer function has nonetheless not been validated in children, and furthermore, its accuracy for derivation of aortic augmentation index has been disputed.^{235–237} The recent introduction of a carotid sensor with multiple micro-piezo-resistive transducers may facilitate the derivation of augmentation index.²¹⁷

Contour analysis of the digital volume pulse has also been used to derive indices attributable to wave reflection.^{238–240} Takazawa et al used the second derivative of the digital photoplethysmogram waveform to identify five distinct waves (Fig. 6-8) and determined their mathematical relationships. In particular, the d/a and b/a ratios have been related to age and arterial stiffness.^{238,241–243} The d/a ratio is also related to aortic augmentation index.²³⁸ However,

Figure 6-7 The augmentation index is calculated from pressure waveforms as the ratio of difference between systolic peak pressure and inflection point (P_i) to pulse pressure (ΔP /pulse pressure). ΔP is (A) positive when peak systolic pressure occurs after the inflection point and becomes (B) negative when peak systolic pressure precedes the inflection point.

Figure 6-8 Five components of the second derivative of photoplethysmogram waveform (SDPTG). This includes four systolic waves (a–d) and one diastolic wave (e). An augmentation index based on photoplethysmogram (PTG) can also be defined as PT_2/PT_1 , where PT_2 is amplitude of the late systolic component and PT_1 is amplitude of the early systolic component. (Reproduced with permission from Takazawa K, Tanaka N, Fujita M, et al: Assessment of vasoactive agents and vascular aging by the second derivative of photoplethysmogram waveform. *Hypertension* 1998;32:365–370.)

the physical and physiological meanings of these measurements remain unclear.

Using similarly photoplethysmographic digital volume pulse waveform, Chowienczyk et al proposed that the first peak in the waveform corresponds to a forward-traveling pressure wave from the heart to the finger, and the second peak or point of inflection to the backward-traveling reflected pressure^{239,240} (Fig. 6-9). A reflection index, defined at the ratio of the magnitude of the reflected wave to the first peak, has been proposed as measure of the amount of reflection, while the peak-to-peak time has been proposed as a surrogate measure of pulse wave velocity and arterial stiffness.^{239,240} An index of large arterial stiffness, defined as height divided by peak-to-peak time, has been shown to be

Figure 6-9 Digital volume pulse and its first derivative. The inflection point is identified by the local maximum in the first derivative. The reflection index, b/a , has been proposed as a measure of amount of reflection. The ratio of ΔT_{DVP} , the time between the first and second peaks, to body height has been used as an index of arterial stiffness. (Reproduced with permission from Chowienczyk PJ, Kelly RP, MacCallum H, et al: Photoplethysmographic assessment of pulse wave reflection. *J Am Coll Cardiol* 1999;34:2007–2014.)

related to pulse wave velocity.²⁴⁴ The simplicity of the digital photoplethysmographic waveform analysis may facilitate large-scale epidemiological studies. These indices, nonetheless, provide at best an indirect assessment of arterial stiffness, and factors affecting their reliability and interpretation in different patient cohorts remain to be clarified.

Blood Pressure Indices

Central pulse pressure, being influenced by wave reflection amongst other factors, is often considered a surrogate of arterial stiffness.²⁴⁵ It should not, however, be used interchangeably as an index of arterial stiffness as their physiological meanings differ. Similar to augmentation index, central pulse pressure is dependent on heart rate, ventricular contractility, and factors affecting the reflected wave, notably arterial stiffness and reflectance points.¹⁷⁵ Peripheral pulse pressure, measured usually at the brachial artery, overestimates central pulse pressure due to the amplification phenomenon, which is more prominent in more elastic arteries such as those in young subjects.²⁴⁶

Recently, an ambulatory arterial stiffness index has been proposed as a novel index of arterial stiffness.^{247,248} Using ambulatory blood pressure monitoring data throughout the day, the index is calculated as 1 minus the regression slope of diastolic blood pressure on systolic blood pressure. This index is based on the concept that average distending pressure varies during the day and that the relation between diastolic and systolic blood pressure, with this changing distending pressure, largely depends on the structural and functional characteristics of the large arteries.²⁴⁸ While this index has been shown to be related to pulse pressure and augmentation index and a predictor of cardiovascular mortality in adults,^{247,248} its physiological meanings and its use as a marker of stiffness remain highly disputed.^{175,249–251}

Endothelial Dysfunction

Endothelial dysfunction is characterised by upset of the regulation of balance between vasodilation and vasoconstriction, inhibition and promotion of vascular smooth muscle proliferation, and prevention and stimulation of platelet aggregation, thrombogenesis, and fibrolysis by the endothelium.²⁵² While the normal quiescent state is represented by nitric oxide-dominated endothelial phenotype and maintained primarily by laminar shear stress,²⁵³ endothelial activation is characterised by dominance of reactive oxygen signaling.²⁵⁴ The common denominator of chronic production of reactive oxygen species potentially exhausts the protective capacity of endogenous anti-inflammatory and anti-oxidative mechanisms and results in sustained endothelial dysfunction. Dysfunction of the endothelium results in loss of its protective function, increased expression of adhesion molecules, and promotion of inflammation within the vessel wall.

Given the important protective role of the endothelium against vascular injury, inflammation, and thrombosis, all of which are key events involved in the initiation and progression of atherosclerosis, it is not surprising that endothelial dysfunction has also prognostic implications. In adults with or without coronary atherosclerosis and in those with hypertension, coronary endothelial dysfunction,^{255–258} impaired flow-mediated dilation of the brachial artery,^{259–261} and impaired agonist-mediated increase in forearm blood

flow^{262,263} have been shown to predict cardiovascular events. With the introduction of a variety of non-invasive techniques as elaborated below for assessment of endothelial function, the phenomenon of endothelial dysfunction has also been documented in an increasing number of paediatric and adolescent conditions.

Assessment of Endothelial Function in Vivo

Coronary Circulation

Assessment of endothelial function in the coronary circulation was first described in 1986 by Ludmer and colleagues²⁶⁴ who demonstrated that local infusion of acetylcholine dilates angiographically normal epicardial coronary arteries secondary to release of nitric oxide from an intact endothelium. By contrast, acetylcholine was found to cause paradoxical constriction of atherosclerotic coronary arteries as a result of direct muscarinic action on vascular smooth muscle. Endothelial function of the coronary resistance vessels can be assessed simultaneously using Doppler flow wires.²⁶⁵ The measurement of changes in coronary arterial diameter, blood flow, and vascular resistance in response to intracoronary infusion of acetylcholine has become the gold standard against which other tests of endothelial function have been compared. Endothelial-independent changes in coronary diameter and flow reserve can be assessed by intracoronary boluses of adenosine or infusion of nitroglycerine. The response to endothelium-independent agonist is assessed to exclude insensitivity of vascular smooth muscle to nitric oxide. In children, coronary endothelial function has been mainly assessed in those with a history of Kawasaki disease. The invasive nature of this technique limits its use to patients in whom cardiac catheterisation is clinically indicated and precludes serial follow-up assessments.

Forearm Resistance Vessels

Endothelial function of forearm resistance vessels is assessed by measurement of forearm blood flow in response to intra-arterial infusion of endothelium-dependent and -independent agonists. Venous occlusion plethysmography has been widely used to measure forearm blood flow.²⁶⁶ The principle of measurement is based on the premise that interruption of venous outflow from the forearm, but not arterial inflow, results in a linear increase in forearm volume with time. In this technique, blood pressure cuffs are placed around the upper arm and the wrist. The forearm is positioned above the heart level to ensure satisfactory venous emptying when cuffs in the upper arm are deflated. The contralateral arm is studied simultaneously to correct for possible changes in basal blood flow with time and to act as control. The upper arm cuff is inflated to around 40 mmHg to occlude venous outflow while allowing arterial inflow into the forearm. The hands are excluded from the circulation by inflating the wrist cuff to supra-systolic blood pressure, as they contain a high proportion of arterio-venous shunts and their blood flow is highly temperature sensitive. The change in forearm volume with continuous arterial inflow is measured using strain-gauge plethysmography. The mercury-in-rubber strain gauges, which act as resistors connected as one arm of a Wheatstone bridge,²⁶⁷ are placed around the right and left forearms. With the increase in forearm volume and circumference, the strain gauges lengthen and increase in

resistance, leading to a potential difference in the Wheatstone bridge circuit. The period of measurement, during which the hands are rendered ischaemic, has been up to 13 minutes in adults.²⁶⁸

A variety of agonists, which include acetylcholine, methacholine, bradykinin, 5-hydroxytryptamine, and substance P, have been used to assess the endothelial-dependent vasodilation response.^{269,270} Of importance to note is that nitric oxide dependence varies among agonists, and indeed, vasodilation caused by methacholine does not appear to be nitric oxide mediated.^{271,272} Apart from stimulation of nitric oxide release, these agonists also induce release of endothelium-derived hyperpolarizing factor and prostaglandins. The response to endothelium-independent agonist, like sodium nitroprusside, is assessed to exclude abnormal vascular smooth muscle function. The forearm blood flow response to endothelial-dependent agonist has been found to correlate with coronary endothelial function^{272,273} and to predict independently cardiovascular events in patients with coronary artery disease.²⁶² The basal release of nitric oxide in the basal forearm can also be assessed using this technique by infusing NG-monomethyl-L-arginine, an L-arginine analogue that inhibits nitric oxide synthase.²⁷⁴ Co-infusion of NG-monomethyl-L-arginine with specific endothelium-dependent agonist can further be used to determine upregulation of alternative vasodilator pathways in condition of endothelial dysfunction.²⁶⁹ This technique is hence invaluable in elucidating mechanisms that underlie endothelial dysfunction. However, as a technique to assess endothelial function, the need for arterial cannulation limits its repeatability and its application in the paediatric population.

Conduit Artery

Non-invasive assessment of flow-mediated dilation of the brachial artery using high-resolution ultrasound was first introduced by Celermajer et al²⁷⁵ in 1992, based on the principle of endothelium-dependent release of nitric oxide in response to shear stress. As alluded to earlier, flow-mediated dilation has been shown to occur predominantly as a result of local endothelial release of nitric oxide.⁸⁵

In this technique, the brachial arterial diameter and Doppler-derived flow velocity is determined at baseline, when the patient has rested in a supine position for at least 10 minutes, and after an increase in shear stress induced by reactive hyperaemia. To induce reactive hyperaemia, a sphygmomanometer cuff, placed either above the antecubital fossa or over the forearm, is inflated to supra-systolic blood pressure and deflated after 4 to 5 minutes. Cuff occlusion of the upper arm has additional direct ischaemic effect on the brachial artery. There is no consensus, however, as to whether cuff occlusion of the upper arm or forearm provides more accurate information.^{276,277} Reactive hyperemia after cuff deflation increases shear stress and leads to dilation of the brachial artery. The maximum increase in flow is assessed within the first 10 to 15 seconds after cuff release, while the brachial arterial diameter is measured at usually 60 seconds after cuff deflation, at a time when maximal dilator response occurs in normal subjects.²⁷⁸ Commercially available automatic edge-detection software allows continuous monitoring of the brachial arterial diameter after cuff deflation and detection of the true peak response (Fig. 6-10). Flow-mediated dilation in the radial, femoral, and posterior tibial arteries can similarly be determined

Figure 6-10 Assessment of brachial arterial flow-mediated dilation. **A**, Ultrasound probe secured in position by a stereotactic clamp for continuous imaging of brachial artery. **B**, Continuous measurement of brachial arterial diameter before and during cuff inflation and after cuff release using automatic edge-detection software. (Reproduced with permission from Deanfield JE, Halcox JP, Rabelink TJ: Endothelial function and dysfunction: Testing and clinical relevance. *Circulation* 2007;115:1285–1295.)

by inflating the cuff at the wrist, just beneath the popliteal fossa, and the ankle, respectively. After at least 10 minutes following cuff release, sublingual nitroglycerine is given to assess endothelium-independent vasodilation. This direct vasodilation response peaks at 3 to 5 minutes after administration of nitroglycerine.

Accurate assessment of flow-mediated dilation is nonetheless challenging. Furthermore, centres differ in the protocols used for elicitation of reactive hyperaemia. The methodological issues, strengths, and limitations of this technique have been explored in depth by the International Brachial Artery Reactivity Task Force²⁷⁹ and the Working Group on Endothelin and Endothelial Factors of the European Society of Hypertension.²⁷⁰ Notwithstanding the skills required and limitations of this technique, its non-invasive nature and its correlation with coronary endothelial function²⁸⁰ have led to its widespread use in clinical trials and in the field of vascular epidemiology.^{281–283} The technique is also widely used for the assessment of endothelial function in children and adolescents, although its application in children younger than 6 years is likely to be difficult given the cooperation needed for accurate measurement of brachial arterial diameter and flow.

Microvasculature

Laser Doppler techniques have been used for the assessment of microvascular endothelial function of the skin.²⁸⁴ The principle of laser Doppler techniques is based on changes in wavelength of the reflected light after hitting moving blood cells. Rather than measuring absolute skin perfusion, these techniques determine red blood cell flux as defined by the product of velocity and concentration of the moving blood cells within the measured volume. Laser Doppler flowmetry is a single-probe technique used to assess the blood flux in a small volume of 1 mm³ or smaller,²⁸⁵ while laser Doppler imaging provides an integrated index over a larger volume by using a mirror to reflect the laser beam to scan a larger skin area.²⁸⁶

To assess microvascular endothelial function, laser Doppler flowmetry and imaging have been used to detect the increase in skin blood flow during reactive hyperaemia after brief arterial occlusion,^{287,288} during local

thermal hyperaemia,^{289,290} and after local application of endothelial-dependent vasodilators by iontophoresis.^{291,292} Nonetheless, the microvascular response to reactive hyperaemia and local heating is complex and depends on mechanisms other than those mediated by the endothelium.^{293–296} Iontophoresis of acetylcholine and sodium nitroprusside has commonly been used to generate endothelium-dependent and endothelium-independent dilation respectively of the skin microvasculature. The applied current can, however, induce vasodilation directly, which is more pronounced with cathodal delivery of acetylcholine and related probably to induction of an axon reflex.²⁹⁷ This effect can be reduced by the use of lower anodal current and larger iontophoresis electrodes. The usefulness of acetylcholine iontophoresis as an assessment of skin microvascular endothelial function has recently been challenged, as acetylcholine-induced vasodilation has been shown to remain unchanged or be only partially attenuated after inhibition of nitric oxide synthase.²⁹⁸ While the test is non-invasive and may reflect to a certain extent the microvascular endothelial function, the poor reproducibility remains an issue of concern. Despite the limitations, acetylcholine iontophoresis coupled with laser Doppler imaging have been used to assess microvascular endothelial function in neonates.²⁹⁹ The latest development of laser flowmetry is quantification of periodic oscillations of skin blood flow by spectral analysis of laser Doppler signals.^{300,301} The oscillations at around 0.01 Hz have been suggested to be endothelium-dependent, although further studies are required to clarify its usefulness as a test for skin microvascular endothelial function.

Emerging Techniques

The aforementioned techniques primarily assess the endothelial-dependent nitric oxide-mediated vasodilation response to agonists. Recent techniques attempted to determine the change in arterial stiffness upon endothelial stimulation. Salbutamol, a β -2 agonist, has been demonstrated to reduce arterial stiffness in a nitric oxide-dependent manner.³⁰² Thus, the changes in augmentation index^{303,304} and the inflection point in the photoplethysmographic digital volume pulse²³⁹ in response to salbutamol

inhalation have been used as measures of endothelial function. However, both of these techniques have been found to be much less reproducible in children when compared with brachial arterial flow-mediated dilation.³⁰⁵ The upper and lower limb pulse wave velocity responses to reactive hyperaemia in the hand and foot have also been used to assess endothelial function.³⁰⁶

The change in digital pulse volume amplitude during reactive hyperaemia, so-called reactive hyperaemia peripheral arterial tonometry, has also been used to assess peripheral microvascular endothelial function^{307,308} (Fig. 6-11). The pattern of the reactive hyperaemia peripheral arterial tonometry has been shown to mirror that of brachial arterial flow-mediated dilation³⁰⁷ and be attenuated in adults with coronary microvascular endothelial dysfunction.³⁰⁸ Recently, the central role for nitric oxide in the augmentation of pulse volume amplitude during reactive hyperaemia in humans has been demonstrated.³⁰⁹

Circulating Biomarkers

While endothelial function is commonly assessed by determining the effects of endothelium-derived nitric oxide on vessel diameter, blood flow, and arterial stiffness, assay of various circulating biomarkers of endothelial and non-endothelial origins may provide additional information on other aspects of endothelial function and magnitude of endothelial activation. These biomarkers include measures of nitric oxide availability, adhesion molecules, inflammatory cytokines, markers of inflammation and oxidative stress, pro- and anti-coagulants, and indices of endothelial cell damage and repair.

The circulating pool of nitric oxide as a measure of its bioavailability can be assessed by measuring plasma nitroso compounds and nitrite.^{310–313} While the exact chemical species of this pool are unclear and their values may be confounded by diet,³¹⁴ recent studies showed that plasma nitrite reflects regional endothelial nitric oxide synthase activity.³¹³ Plasma nitrite reserve during reactive hyperaemia³¹¹ and plasma nitroso compounds³¹⁰ have been found to be reduced in the presence of endothelial dysfunction. Reduced nitric oxide availability can also be inferred from

elevated levels of the naturally occurring antagonist of nitric oxide synthase, dimethylarginine,³¹⁵ which has been shown to be associated with cardiovascular disease and mortality in adults.³¹⁶ Activation of endothelial cells upregulates the expression of adhesion molecules. The levels of circulation adhesion molecules, including intercellular adhesion molecule 1, vascular cell adhesion molecule 1, E-selectin, and P-selectin can be determined using commercially available assays. Interaction of the dysfunctional endothelium with circulating leucocytes, in which the adhesion molecules play a crucial role,^{317,318} initiates inflammation within the vessel wall. Furthermore, oxidative stress, an important determinant of inflammation, is increasingly recognised to play an important role in compromising endothelial function.^{319,320} Thus, the levels of inflammatory markers, including high-sensitivity C-reactive protein, interleukin-6, and tumor necrosis factor- α , and markers of oxidative stress, such as oxidised low-density lipoprotein and 8-iso-prostaglandin F₂ α , can be used to reflect ongoing endothelial activation and vascular inflammation.

Disturbance of the protective role of the endothelium against thrombosis in endothelial dysfunction is reflected by the imbalance between endothelium-derived tissue plasminogen activator and plasminogen activation inhibitor-1³²¹ and the release into circulation of von Willebrand factor.³²² Measurement of the dynamic release of tissue-plasminogen activator by agonists such as bradykinin, substance P, methacholine, and desmopressin has been used to assess endothelial function,^{323–326} although data on its relationship with cardiovascular risk factors and prognostic values is limited.

There is increasing interest in the role of endothelial microparticles and endothelial progenitor cells as markers and risk factors of endothelial dysfunction and cardiovascular disease. Damage to endothelial cells can result in their detachment into the circulation in entirety or as microparticles. Endothelial microparticles have been found to be increased in vasculitis and atherosclerotic diseases.^{327–330} The quantity of circulating endothelial cells and microparticles is therefore a potentially useful marker of endothelial function. Interestingly, recent evidence suggests that

Figure 6-11 Reactive hyperaemia peripheral arterial tonometry recordings of individuals with normal and abnormal responses. (Reproduced with permission from Bonetti PO, Pumper GM, Higano ST, et al: Noninvasive identification of patients with early coronary atherosclerosis by assessment of digital reactive hyperemia. *J Am Coll Cardiol* 2004;44:2137–2141.)

endothelial microparticles may contribute directly to endothelial dysfunction.^{328,331} With regard to the repair of damaged endothelium, apart from proliferation of local mature endothelial cells, the importance of bone-marrow derived endothelial stems cells and endothelial progenitor cells is increasingly recognised.^{332–334} Mobilisation of endothelial progenitor cells is in part nitric oxide-dependent.³³⁵ Furthermore, the number of progenitor cells has been shown to correlate negatively with the cardiovascular risk score and positively with brachial arterial flow-mediated dilation in adults.³³⁶ The level of endothelial progenitor cells may hence be a novel marker of endothelial function, vascular dysfunction, and cardiovascular risk in adults. The usefulness of endothelial microparticles and endothelial progenitor cells as markers of endothelial function in the paediatric population awaits further clarification.

SYSTEMIC ARTERIAL DYSFUNCTION IN CHILDHOOD

Age-related Evolution

Progressive increase in aortic, upper limb, and lower limb pulse wave velocities, as measured by transcutaneous Doppler technique, with age in a cohort of subjects aged 3 to 89 years has been reported.³³⁷ Age-dependent increase in brachio-radial arterial pulse wave velocity has similarly been demonstrated in a cohort of children and adolescents aged 6 to 18 years using the photoplethysmographic technique.³³⁸ Using the area under the ascending aortic pressure-time curve to determine the total stiffness of the arterial tree and assuming a two-element *Windkessel* model, a non-linear increase in total arterial stiffness in children aged 6 months to 20 years has been demonstrated.³³⁹ Although a nadir of arterial stiffness at around 10 years of age has been reported,³⁴⁰ this has not been replicated in subsequent studies.

Notwithstanding the influence of the distending pressure on arterial stiffness, previous findings did not suggest that the change in pulse wave velocity with age is entirely due to differences in systemic blood pressure.^{337,338} Rather, the gradual increase in arterial stiffness with age is probably related to progressive medial degeneration. With cyclical mechanical stress, fragmentation of the elastin fibres and transfer of stress to the much stiffer collagen fibres inevitably result in progressive increase in vascular stiffness.³⁴¹ Furthermore, studies of developmental changes in arterial structure during childhood have demonstrated progressive increase in intimal and medial thickness after birth.³⁴² Hence, the observed age-related increase in stiffness is likely related to progressive structural changes in the arterial wall during childhood.

In otherwise healthy adult subjects, endothelial function has been shown to deteriorate with aging.³⁴³ Furthermore, progressive endothelial dysfunction appears to occur earlier in men than in women. While puberty has been speculated to be a critical period for the vascular endothelium,³⁴⁴ this requires further clarification.

Cardiovascular Risk Factors

Childhood obesity has become a global epidemic. In obese children, increased stiffness of the abdominal aorta^{345,346} and carotid artery³⁴⁷ has been demonstrated. Endothelial

dysfunction is evidenced by elevated serum biomarkers of endothelial activation^{348,349} and impaired brachial arterial flow-mediated dilation.^{347,350–352} Studies have further shown that in obese children, endothelial dysfunction improves with exercise training.^{353–355} Concomitant cardiovascular risk factors linked with arterial dysfunction often occur in obese children and these include dyslipidaemia, diabetes mellitus, and low-grade inflammation. Indeed, endothelial dysfunction in obese prepubertal children has recently been shown to be related to insulin resistance and markers of inflammation.³⁵⁶ Obese children who have concomitant metabolic syndrome were found to have stiffer common carotid artery than those without.³⁵⁷ Furthermore, a strong graded inverse association between number of components of metabolic syndrome and brachial arterial distensibility has been demonstrated.³⁵⁸ The effects of obesity-related peptides on vasculature are increasingly recognised.³⁵⁹ Elevations in leptin have been shown to be associated with impaired arterial distensibility in healthy children³⁶⁰ and in children with type 1 diabetes.³⁶¹ The effect of leptin on endothelial function in humans is, however, controversial.³⁶² Plasma adiponectin, on the other hand, has been shown to correlate with vasodilator response of the forearm microcirculation to reactive hyperaemia.^{363,364}

In children with heterozygous familial hypercholesterolaemia increased stiffness of the common carotid artery^{365,366} and modification of the aortic elastic properties³⁶⁷ have been demonstrated. Impaired brachial arterial flow-mediated dilation has also been shown in these children and in those with familial combined hyperlipoproteinaemia at as young as 6 years of age.^{275,368–370} Endothelial dysfunction is most pronounced in those with a positive family history of premature cardiovascular disease.³⁷¹ Early statin and antioxidant vitamins C and E therapy may potentially restore endothelial dysfunction in these children towards normal.^{369,370,372} However, the relationship between flow-mediated dilation and low-density lipoprotein cholesterol levels is controversial.^{365,368,369} On the other hand, in a population-based study, total and low-density lipoprotein cholesterol levels were found to relate inversely to brachial arterial distensibility,³⁷³ suggesting the possibility that cholesterol levels in the general population during childhood may already be of relevance in the pathogenesis of arterial stiffening.

Children with type 1 diabetes have well-documented endothelial dysfunction,^{374–377} which has been shown to improve by folic acid.³⁷⁸ Arterial stiffening in these children is further suggested by an increase in augmentation index,³⁷⁹ and has recently been found to be associated with nitric oxide synthase 3 polymorphism.³⁸⁰ Offspring of parents with type 2 diabetes have a high risk of developing diabetes and atherosclerotic complications. Studies have shown increased aortic³⁸¹ and carotid-radial³⁸² pulse wave velocity in normoglycaemic who are offspring of parents with type 2 diabetes. Impaired brachial arterial flow-mediated dilation has similarly been shown in first-degree adult relatives of type 2 diabetic patients.^{383–387} Whether such arterial dysfunction has its onset in childhood is unknown.

Structural alterations of the common carotid artery with intima-media thickening have been found in children and adolescents with a parental history of premature myocardial infarction.³⁸⁸ In adults who are offspring of parents with premature cardiovascular disease, apart from intima-media

thickening, impaired endothelial-dependent vasodilation of brachial artery has also been found.^{389,390}

Habitual physical activity in children aged 5 to 10 years has been shown to correlate positively with flow-mediated dilation, suggesting that its cardiovascular protective effect may be mediated via the endothelium.³⁹¹ In another cohort of 10-year-old children, physical activity was found to correlate inversely with arterial stiffness as assessed by measuring the aorto-femoral and aorto-radial pulse wave velocities.³⁹²

Apart from the traditional cardiovascular risk factors, novel risk factors have also been shown to be associated with arterial dysfunction in children. Associations between increased baseline high-sensitivity C-reactive protein concentrations and the risks of developing cardiovascular disease in adults have been reported.^{393–395} Furthermore, *in vitro* studies showed that C-reactive protein induces adhesion molecule expression in human endothelial cells.³⁹⁶ In healthy children, serum high-sensitivity C-reactive protein concentrations have been found to have an inverse dose-dependent relationship with the magnitude of brachial arterial flow-mediated dilation.³⁹⁷ Increased serum high-sensitivity C-reactive protein levels are found in obese adolescents.^{351,398} Analysis of the 1999–2000 National Health and Nutrition Examination Survey indeed showed a strong independent association between body mass index and C-reactive protein level even in young children aged 3 to 17 years.³⁹⁹ However, in children and adolescents who do not have much of an atherosclerotic burden, whether high-sensitivity C-reactive protein is a risk factor or a risk marker requires further clarification.

In children with homozygous homocystinuria, impaired brachial arterial flow-mediated dilation has been demonstrated in those as young as 4 years.⁴⁰⁰ In the general paediatric population, findings of elevated homocysteine levels in children with a family history of premature cardiovascular disease are conflicting.^{401–403} Although hyperhomocysteinaemia is a risk factor for endothelial dysfunction in middle-aged⁴⁰⁴ and elderly⁴⁰⁵ subjects, there is as yet no data to suggest a link between arterial dysfunction and serum homocysteine levels in children.

Prenatal Growth Restriction

It has almost been two decades since the report of associations between low birth weight and increased risk of cardiovascular disease.⁴⁰⁶ These findings, having been replicated in subsequent studies,^{407–409} have formed the basis of the fetal origins hypothesis that implicates the origin of cardiovascular disease from adaptations to an adverse environment in utero. These adaptations have been proposed to cause permanent alterations of cardiovascular structure and physiology through the process of programming.

There is evidence that individuals who are born small are at risk of vascular dysfunction in childhood and adulthood. Arterial endothelial dysfunction has been found in term infants,²⁹⁹ children,⁴¹⁰ and young adults⁴¹¹ with low birth weight. A recent study showed elevated uric acid in children with low birth weight and a graded inverse relationship between uric acid and flow-mediated dilation.⁴¹² In children born at term, leanness at birth has been reported to correlate with the lowest endothelium-dependent microvascular responses and the highest carotid stiffness

indices.⁴¹³ In infants with umbilical placental insufficiency before birth, the increase in afterload has been shown to result in a decrease in aortic distensibility during the neonatal period, suggesting an alteration of aortic wall structure.⁴¹⁴ Furthermore, reduced compliance of the aorta and conduit arteries of the legs has been shown to occur in adults born small.⁴¹⁵

The risk of arterial dysfunction for individuals who are born small as a result of prematurity is controversial. An increase in systolic blood pressure has been shown in a cohort of young adults born prematurely, regardless of whether or not they had intra-uterine growth retardation.⁴¹⁶ On the other hand, only individuals who had been preterm babies with intra-uterine growth retardation were found to have impaired brachial arterial flow-mediated dilation.⁴¹⁷ Nonetheless, preterm birth has also been demonstrated to attenuate the association between low birth weight and endothelial dysfunction.⁴¹⁸ With regard to arterial stiffness, reduced aortic wall distensibility and whole-body compliance have been shown in very low birth weight premature infants as early as the neonatal period.⁴¹⁹ Other studies have demonstrated inverse relationships between systemic arterial stiffness and gestational age⁴²⁰ and birth weight standardised for gestational age.⁴²¹

In monozygotic twins with twin-twin transfusion syndrome, the growth-restricted donor twin provides a unique model for studying the effects of differing volume load and increased placental resistance on the developing cardiovascular systems in two genetically identical individuals. A previous study has shown that the peripheral conduit arterial stiffness is increased during infancy in the donor twins.⁴²² Such vascular programming has been shown to be ameliorated, albeit not completely abolished, by intra-uterine endoscopic laser ablation of placental anastomoses.⁴²³ Even in monozygotic twins without twin-twin transfusion syndrome, the twin with the lower birth weight has been found to have higher systolic blood pressure and pulse pressure and impaired endothelial function in childhood.⁴²⁴

The mechanism whereby low birth weight is associated with increased arterial stiffness in childhood and adulthood remains unclear. The reported endothelial dysfunction in individuals born preterm and small-for-gestational age^{299,410,411,415,417} suggests that functional alteration of arterial tone may contribute to an increase in systemic arterial stiffness. Altered haemodynamics in intra-uterine growth retardation, which result in preferential perfusion of upper part of body,⁴²⁵ may affect the mechanical properties of the large arteries. Hence, selective carotid arterial atherosclerosis has been found to be more severe in elderly people with the lowest birth weight.⁴²⁶ Another proposed mechanism is the impairment of synthesis of elastin in the arterial wall.³⁴¹ In the donor twin in twin-twin transfusion syndrome, the superimposed circulatory imbalance probably acts synergistically with growth restriction to cause the vascular programming, although the exact mechanism remains to be defined.⁴²² The exact mechanism of endothelial dysfunction in individuals with low birth weight is even more elusive.

Nutritional Issues

The associations between early growth restriction and arterial dysfunction highlight the potential importance of nutrition in antenatal and early postnatal life on long-term

vascular programming. Leeson et al studied in a young adult population-based cohort the relation between duration of breast-feeding and brachial arterial distensibility.⁴²⁷ They found an inverse relation between duration of breast-feeding and arterial distensibility even after adjusting for current lipid profile, body mass index, and social class. A recent study in 10-year-old children also demonstrated a positive association between breast-feeding and stiffness of the aorto-femoral arterial segment as determined by pulse wave velocity.³⁹² Despite these findings that evoked much comment, it is important to realise that there is to date little consistent evidence that breast-feeding influences subsequent mortality related to cardiovascular disease⁴²⁸ and that the current advice on breast-feeding practise has not been altered by these findings.

In children receiving long-term parenteral nutrition, significant increase in elastic modulus of the common carotid artery and impairment of brachial arterial flow-mediated dilation have been demonstrated.⁴²⁹ While the mechanisms are unclear, infusion of lipid emulsions or high-concentration dextrose has caused endothelial damage and vascular remodeling in animal models.^{430,431} It remains unknown whether vascular dysfunction is reversible after reestablishment of enteral feeding.

Childhood Vasculitides

Kawasaki disease, a childhood vasculitis of unknown etiology, is the commonest cause of acquired heart disease in children in developed countries (see Chapter 52). The sequelae of inflammation involving coronary and other medium-sized muscular arteries in the acute phase of the disease are well documented.^{432–434} Long-term structural alteration and functional disturbance of coronary arteries also have long been known.^{432–436} Systemic arterial dysfunction is increasingly recognised in children with a history of Kawasaki long term after the acute illness. Indeed, concerns have been raised regarding the possibility of its predisposition to premature atherosclerosis in adulthood.^{437–441}

Impaired brachial arterial flow-mediated dilation has been demonstrated in patients, even in those without early coronary arterial involvement, studied at a median of 11 years after the acute illness.⁴⁴² Intravenous administration of vitamin C has been shown to improve the impaired flow-mediated dilation.⁴⁴³ Increased stiffness of the carotid artery^{444,445} and brachioradial artery,⁴⁴¹ relating in a dose-dependent manner to the degree of coronary arterial involvement, has also been documented in the long-term follow-up of these patients. By measuring aortic input impedance during cardiac catheterisation, Senzaki et al⁴⁴⁶ found that both characteristic impedance and total peripheral arterial compliance were reduced in Kawasaki patients regardless of persistence of coronary artery aneurysms, suggesting an increase in both central and peripheral arterial stiffness. Chronic low-grade inflammation, as reflected by elevated high-sensitivity C-reactive protein,^{447,448} in patients with coronary aneurysm formation has been associated positively with carotid arterial stiffness.⁴⁴⁷ Indeed, histological evidence of extensive fibro-intimal thickening and infiltration of lymphocytes and plasma cells in the coronary arterial walls has been documented in fatal cases of Kawasaki disease occurring years after apparent resolution of vascular inflammation and in the absence of early detectable

coronary arterial abnormalities.⁴⁴⁹ In vitro evidence further suggests that chronic activation of the monocyte chemoattractant protein-1/chemokine receptor CCR2 pathway and inducible nitric oxide synthase may play a role in chronic low-grade inflammation in Kawasaki patients.⁴⁵⁰ Besides, modulating effects of mannose-binding lectin genotype on arterial stiffness are suggested by findings of patients with intermediate- or low-level expression genotypes having faster brachioradial arterial pulse wave velocity than those with high-level expression genotypes.⁴⁵¹

Limited data exists for systemic arterial dysfunction in other types of childhood vasculitis. Transient impaired forearm vascular endothelium-dependent relaxation has been found in children during the acute phase of Henoch-Schoenlein purpura.⁴⁵² In children with polyarteritis nodosa, a chronic vasculitis characterised by recurrent episodes of inflammatory exacerbations, stiffening of the brachioradial artery with amplification during episodes of inflammatory exacerbation has been demonstrated.³³⁸ Endothelial microparticles has also been found to be significantly increased in children with systemic vasculitis and to correlate with disease activity score.⁴⁵³

Vasculopathies in Syndromal Disorders

Marfan syndrome is caused by mutations of the *fibrillin-1* gene.⁴⁵⁴ Fibrillin-1, as mentioned earlier, is a matrix glycoprotein and is the principal constituent of microfibrils. Increased aortic stiffness is well documented in patients with Marfan syndrome, as shown by the decreased distensibility and increased stiffness index,^{455–463} increased pulse wave velocity,⁴⁶⁴ and decreased tissue Doppler-derived systolic and diastolic velocities of the aortic wall.⁴⁶⁵ Apart from structural alterations, impaired flow-mediated dilation, possibly related to a defective role of subendothelial fibrillin in endothelial cell mechanotransduction,⁴⁶⁶ may also contribute to arterial stiffening. In an animal model of Marfan syndrome, down-regulation of signaling of nitric oxide production in the thoracic aorta has recently been shown to account for endothelial dysfunction.⁴⁶⁷ While correlation between *fibrillin-1* genotype and aortic stiffness is poor,⁴⁶⁸ aortic stiffness has been shown to be an independent predictor of progressive aortic dilation^{469,470} and aortic dissection.⁴⁷⁰ Beta-blocker therapy⁴⁶⁴ and angiotensin-converting enzyme inhibition⁴⁷¹ appear to reduce aortic stiffness, which may in turn slow aortic dilation and delay aortic root replacement.⁴⁷¹

Williams syndrome is a contiguous gene disorder with chromosomal microdeletion at 7q11.23, which encompasses the elastin gene and the genes nearby.^{472,473} Haploinsufficiency of the elastin gene has been implicated in the arteriopathy of Williams syndrome.⁴⁷⁴ Despite a biological basis for abnormal elastic fibres, results of studies exploring arterial elastic properties in patients with Williams syndrome are controversial. Studies have shown increased stiffness of the ascending aorta and aortic arch and implied that abnormal mechanical property of the arteries may contribute to systemic hypertension, which is common in patients with Williams syndrome.^{475,476} By contrast, paradoxical reduction of stiffness of the common carotid artery has also been reported.^{477,478} The authors speculated that abnormal elastic fibre assembly in the media may shift the load-bearing structures in the arterial wall to those with a lower elastic modulus.

Systemic arterial abnormalities are common in Turner's syndrome, which include bicuspid aortic valve, coarctation of the aorta, and aneurysmal dilation of the aortic root. Although histological evidence of cystic medial necrosis has been reported in Turner's syndrome,^{479,480} these findings are not consistently present. Functionally, carotid augmentation index has been found to be increased, explainable in part by the short stature, while carotid-femoral pulse wave velocity and brachial arterial flow-mediated dilation remain normal in these patients.^{481,482} It is worthwhile to note, however, that isolated bicuspid aortic valve is associated with progressive dilation of the ascending aorta in both children and adults⁴⁸³ and increased aortic stiffness.^{484,485}

Congenital Heart Disease

Aortic medial abnormalities with elastic fibre fragmentation have been identified in intra-operative biopsies and necropsy specimens in a variety of congenital heart disease in patients ranging from neonates to adults.⁴⁸⁶ These congenital heart lesions include tetralogy of Fallot with or without pulmonary atresia, truncus arteriosus, complete transposition of the great arteries, coarctation of the aorta, double outlet ventricles, and univentricular hearts. Whether these abnormalities are inherent or acquired is, however, unknown.

Intrinsic histological abnormalities as characterised by medionecrosis, fibrosis, and elastic fragmentation of the aortic root and ascending aorta have been implicated in causing subsequent aortic root dilation in patients after surgical repair of tetralogy of Fallot.^{487–489} The potential alterations of aortic mechanical properties have also been studied. In children and adolescents with tetralogy of Fallot, aortic stiffness has been shown to be increased and related to the aortic root dimensions.⁴⁹⁰ A subsequent study demonstrated preferential stiffening of the central over peripheral conduit arteries as evidenced by increased heart-femoral pulse wave velocity without concomitant increase in femoral-ankle pulse wave velocity.⁴⁹¹ Importantly, the heart-femoral pulse wave velocity and carotid augmentation index were found to be significant determinants of the size of sinotubular junction, suggesting that central arterial stiffening may contribute to progressive aortic root dilation in these patients.

In transposition of the great arteries, abnormal aortico-pulmonary septation has been hypothesised to be associated with events in elastogenesis.^{492,493} As described earlier, medial abnormalities have been found in this congenital heart anomaly.⁴⁸⁶ In patients undergoing two-stage anatomical correction, decreased distensibility of the neo-aorta has been thought to be related to pulmonary arterial banding.⁴⁹⁴ Nonetheless, even after one-stage arterial switch operation, impaired distensibility of the neo-aorta has similarly been found.⁴⁹⁵ Recent studies further documented increased stiffness index of the carotid artery in patients after both atrial and arterial switch operations,^{493,496} suggesting that impaired elastogenesis may be an intrinsic component of this congenital anomaly.

Structural abnormalities of the aortic segment proximal to the site of aortic coarctation are characterised by increase in collagen and decrease in smooth muscle content.⁴⁹⁷ Functionally, impaired flow-mediated dilation, reduced

nitroglycerine-induced vasodilation, and increased pulse wave velocity were found to be confined to conduit arteries proximal to the site of coarctation despite successful surgical repair.^{498–500} The distensibility of the aortic arch has likewise been shown to be significantly lower than that of the distal thoracic aorta.⁵⁰¹ Furthermore, analysis of the ascending pressure waveform obtained during cardiac catheterisation revealed enhanced aortic pressure wave reflection as evidenced by a short time to inflection point and increased augmentation index.⁵⁰² This has been hypothesised to be related to a major reflection point at the site of coarctation repair. The finding of an inverse relationship between the magnitude of brachial artery vasodilation response to nitroglycerine and 24-hour systolic blood pressure implicates a possible role of reduced vascular reactivity in the development of systemic hypertension and left ventricular hypertrophy in patients late after successful repair of coarctation.⁵⁰⁰ The importance of early coarctation repair on possible prevention of late vascular dysfunction is highlighted by the inverse relationships found between age at repair and stiffness and vascular reactivity of the pre-coarctation arterial segments.^{499,501,503} Nonetheless, the results of a recent study suggest that impaired elastic properties of the prestenotic aorta may be a primary abnormality, as evidence by increased ascending aortic stiffness index in neonates with coarctation even pre-operatively.⁵⁰⁴

Endothelial dysfunction has also been associated with congenital heart anomalies. In adults with cyanotic congenital heart disease, impaired forearm blood flow response to intra-arterial infusion of acetylcholine has been shown.⁵⁰⁵ The cause is probably multi-factorial, being related to reduced nitric oxide production,⁵⁰⁶ hypoxaemia,⁵⁰⁷ and secondary erythrocytosis.⁵⁰⁸ Altered levels of biomarkers of endothelial activation have been shown in a small cohort of children and adolescents with univentricular hearts who have undergone cavopulmonary connection.⁵⁰⁹ In patients after the Fontan operation, reduced brachial arterial flow-mediated dilation,^{510,511} and, in a subset, impaired nitroglycerine-induced vasodilation⁵¹¹ have been demonstrated. A negative correlation, albeit weak, was found in post-Fontan patients between flow-mediated dilation and serum levels of nitric oxide pathway inhibitors, asymmetric and symmetric dimethylarginine.⁵¹⁰ Furthermore, those on angiotensin-converting enzyme inhibitor tended to have better endothelial function. The usefulness of angiotensin-converting enzyme inhibitor in the post-Fontan state nonetheless remains debatable.

Systemic Diseases

Inflammation plays a pivotal role in the pathogenesis of atherosclerosis and cardiovascular disease.⁵¹² The association between low-grade chronic inflammation and endothelial dysfunction has been discussed earlier. Rheumatoid arthritis and systemic lupus erythematosus provide clinical models for determining relationships between chronic systemic inflammation and arterial stiffness and endothelial dysfunction. In adults, rheumatoid arthritis has been associated with increased arterial stiffness^{513–518} and endothelial dysfunction.^{519–522} In the only available study of children with juvenile rheumatoid arthritis to date, Argyropoulou and colleagues reported increased pulse wave velocity and reduced distensibility of the aorta,⁵²³ as determined by

phase contrast magnetic resonance, although these parameters were not found to be related to disease activity parameters. Few studies have evaluated arterial function in children with systemic lupus erythematosus. In women with systemic lupus erythematosus, brachial artery flow-mediated dilation has been found to be impaired^{524,525} and carotid arterial stiffness increased.^{518,526} In adolescents and young adults with paediatric onset lupus, endothelial function has been found to be normal.⁵²⁷ However, a recent study demonstrated increased carotid arterial stiffness, which is associated with left ventricular hypertrophy and subclinical left ventricular dysfunction.⁵²⁸

Apart from intrinsic chronic inflammatory stimuli, acute exposure to extrinsic inflammatory insult in children who had an acute infection or are convalescing from an infection in the previous 2 weeks has been shown to cause transient impairment of brachial arterial flow-mediated dilation.⁵²⁹ The endothelial dysfunction was found to recover in most but not all of the children studied at follow-up 1 year later. Possible mechanisms include a direct effect of virus⁵³⁰ or an indirect effect through inflammatory cytokines on endothelial function. Apart from common acute childhood infections, chronic infection with human immunodeficiency virus in children has been associated with arterial dysfunction. The functional alteration is characterised by impaired brachial arterial flow-mediated dilation^{531,532} and increased elastic modulus of the carotid arterial wall.⁵³¹ Additionally, endothelial dysfunction was found to be more pronounced in children receiving protease inhibitor therapy.⁵³² Whether these vascular changes are related to metabolic abnormalities such as dyslipidemia and insulin resistance secondary to antiretroviral therapy^{533,534} is uncertain. On the other hand, the direct virus-induced and indirect cytokine activation of endothelium⁵³¹ may account for the observed arterial dysfunction.

In adults with chronic renal failure, premature atherosclerosis is a major cause of morbidity and mortality. Recent evidence suggests that children with end-stage renal failure are similarly subjected to increased risk of cardiovascular disease.⁵³⁵ Increased aortic pulse wave velocity and carotid arterial stiffness have been shown to be an independent predictor of cardiovascular mortality in adults with end-stage renal failure.^{186,187,536} In children on haemodialysis, increased carotid-femoral pulse wave velocity and augmentation index have also been demonstrated,⁵³⁷ although the prognostic significance of these indices in children is unknown. Even after successful renal transplantation, the carotid arterial stiffness in children and adolescents remains elevated and is found to be associated with higher daytime systolic blood pressure load and receipt of cadaveric kidney.⁵³⁸ Apart from arterial stiffening, endothelial dysfunction has been shown in children with chronic renal failure, even in the absence of classic cardiovascular risk factors,⁵³⁹ and in those after transplantation.⁵⁴⁰ Limited evidence suggests that oral folic acid, but not L-arginine, may improve endothelial function in children with chronic renal failure by lowering homocysteine level and increasing resistance of low-density lipoprotein to oxidation.^{541,542}

Increased iron store has been linked to the risk of atherosclerosis.⁵⁴³ Iron-overloading in patients with β -thalassaemia major results in alterations of arterial structures with disruption of elastic tissue and calcification.^{544,545} Functional disturbance of human vascular endothelial cells

when being incubated with thalassaemic serum has further been demonstrated in vitro.⁵⁴⁶ In adolescent and adult patients with β -thalassaemia major, increased stiffness of the carotid artery, brachioradial artery, and aorta has been shown in vivo.^{547,548} Importantly, systemic arterial stiffening is inversely related to brachial arterial flow-mediated dilation and positively with left ventricular mass and carotid intima-media thickness.^{547,549} In a mouse model of β -thalassaemia major, the Pourcelot index, a parameter that depends on arterial compliance, downstream vascular resistance, and total peripheral vascular resistance was found to be increased.⁵⁵⁰ This result corroborates the findings of elevated pulsatile and static afterload in patients with β -thalassaemia major.⁵⁵¹ Apart from oxidative damage related to iron overload, the cell-free haemoglobin in haemolytic disease has also been implicated in mediating vascular dysfunction by limiting nitric oxide availability.⁵⁵²

Sleep-related disorders are common in children and may potentially affect arterial function. While relationship between snoring and cardiovascular complications in adults has been controversial,^{553–558} in children with primary snoring, higher daytime systemic blood pressure and increased brachioradial arterial stiffness has been reported.⁵⁵⁹ In adults with obstructive sleep apnea, increased carotid-femoral pulse wave velocity and brachial-ankle pulse wave velocity have been reported.^{560,561} Acute increase in radial arterial stiffness during episodes of apnea has also been shown.⁵⁶² While the exact mechanisms are unknown, hypoxia, increased vasoconstrictors, enhanced vasoconstrictor sensitivity, and increased sympathetic tone might account for the alteration of arterial elastic properties.^{556–558,560,563,564} Endothelial dysfunction has been shown in adults with obstructive sleep apnea,^{565–567} which is potentially reversible by nasal continuous positive airway pressure.^{568,569} Whether arterial dysfunction exists in paediatric patients remains to be clarified.

In children with MELAS (mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke), the level of L-arginine has been found to be significantly lower during stroke-like episodes and associated with reduced brachial arterial flow-mediated dilation.^{570–572} Prolonged L-arginine supplementation has been shown to reduce the stroke-like episodes and normalise endothelial dysfunction.^{571,572}

Genetic Considerations

The genetic aspect of arterial stiffness is increasingly being unveiled. The phenomenon of arterial stiffening in genetic syndromes associated with mutations or deletion of genes encoding structural proteins of the arterial wall has been alluded to earlier. Marfan and Williams syndromes are examples whereby genes exert influence on systemic arterial stiffness. Studies have demonstrated significant heritabilities of common carotid artery stiffness, augmentation index, and carotid-femoral pulse wave velocity in different ethnic populations.^{573–576} Microarray analysis of the transcriptome of aortic specimens obtained from adults with coronary artery disease has revealed correlations between aortic stiffness and expression of two groups of genes, namely, those associated with cell signaling and those associated with mechanical regulation of vascular structure.⁵⁷⁷ Indeed, the influence of *matrix metalloproteinase-3* and *-9* genotypes on aortic stiffening in healthy elderly subjects

has been reported.^{578,579} Studies have also related arterial stiffness to polymorphisms of candidate genes, including those involved in the renin-angiotensin-aldosterone system^{580–582} and endothelin receptors.⁵⁸³ In adults with coronary artery disease, *fibrillin-1* genotype is associated with aortic input and characteristic impedance and disease severity.⁵⁸⁴ Whether *fibrillin-1* genotype is similarly associated with aortic stiffening in healthy adults is, however, controversial.^{585,586} In children, gene polymorphism of the mannose-binding lectin, a body defence molecule, has been found to exert modulating influence on arterial stiffness after vasculitic damage in patients with a history of Kawasaki disease, as discussed earlier,⁴⁵¹ while arterial stiffening in children with type 1 diabetes is associated with *nitric oxide synthase 3* polymorphism.³⁸⁰ Recently, a genome-wide scan identified linkage of carotid-femoral pulse wave velocity to several separate genetic loci in humans.⁵⁷⁶

Potential genetic contribution to endothelial dysfunction is evidenced by studies demonstrating that young individuals with a family history of cardiovascular disease have impaired endothelial function^{389,390} and that polymorphisms of angiotensin-converting enzyme⁵⁸⁷ and endothelial nitric oxide synthase genes⁵⁸⁸ may influence endothelial function. In children, endothelial dysfunction has been documented in single-gene disorders including homocystinuria⁴⁰⁰ and familial hypercholesterolemia.^{275,368–370} In a large community-based sample, the estimated heritability of brachial artery flow-mediated dilation has been shown to be modest.⁵⁸⁹ While polymorphisms of genes encoding factors involved in the regulation of nitric oxide synthesis have been implicated in endothelial dysfunction,⁵⁹⁰ further studies are warranted before any conclusions can be drawn.

Clinical Implications

The prognostic implications of arterial dysfunction in adults have been alluded to earlier. In children and adolescents, the predictive value of these measures of arterial dysfunction for future cardiovascular events is unclear. It appears unrealistic, however, to assess prognostic value of indices of arterial function in childhood only in terms of end-points such as cardiovascular morbidity and mortality. Structural surrogate measures of atherosclerosis, such as carotid intima-media thickness, are potentially useful alternatives.⁵⁹¹ Indeed, increased carotid intima-media thickness has been associated with several of the aforementioned paediatric conditions including familial hypercholesterolaemia,^{592–594} type 1 diabetes,^{374,594} family history of premature myocardial infarction,³⁸⁸ children infected with human immunodeficiency virus on antiretroviral therapy,⁵⁹⁵ obese children with insulin resistance,⁵⁹⁶ and thalassaemia major.⁵⁴⁹ Nonetheless, whether arterial stiffening and endothelial dysfunction represent genuine childhood cardiovascular risk factors awaits further clarification.

Early identification of arterial dysfunction that potentially precedes and induces atherosclerotic changes provides a window for early intervention. The potential beneficial effects on endothelial function of folic acid in children with renal failure,^{541,542} antioxidant vitamins and statins in those with familial hypercholesterolaemia,^{369,371,372} vitamin C in those with Kawasaki disease,⁴⁴³ and exercise training in obese children^{353,597} were alluded to earlier. In patients

with Marfan syndrome, β -blocker therapy⁴⁶⁴ and angiotensin-converting enzyme inhibition⁴⁷¹ appear to reduce aortic stiffness. Longitudinal studies are required to determine whether improvement of arterial function will be translated into clinical benefits. In healthy children, whether such lifestyle and dietary modifications have any effects on the prevention of arterial dysfunction remains to be substantiated.

Given that the systemic arterial system receives and distributes output from the systemic ventricle, satisfactory performance of the systemic ventricular pump depends on not only its intrinsic properties but also its optimal interaction with the systemic circulation. Dysfunction of either of the components of the cardiovascular system would inevitably affect performance of the other. This issue of ventriculo-arterial interaction is discussed in the following section.

VENTRICULO-ARTERIAL INTERACTION

Impact of Arterial Dysfunction on Ventricular Function

From the cardiac perspective, arterial dysfunction exerts its influence on systemic ventricular afterload, energetic efficiency, structure, function, and coronary arterial perfusion. As discussed earlier, ventricular afterload is increased in the presence of systemic arterial stiffening and endothelial dysfunction, the latter through modulation of vascular tone. To generate the same stroke volume against a stiffened arterial tree, the systemic ventricle has to generate a higher end-systolic pressure. As the pressure developed during systole is a major determinant of myocardial oxygen consumption, greater energy cost to the heart is required. In a canine model in which a Dacron graft was sewn to replace the descending aorta, increased cardiac workload, increased myocardial oxygen consumption by 30% to 50%, and reduced cardiac efficiency, defined as ratio of stroke work to oxygen consumption, by an average of 16% have been found.^{598,599} Structural adaptation of the left ventricle to increased afterload is also evident in the presence of arterial stiffening. In a rat model of aortic elastocalcinosis, isolated increased aortic stiffness but without changes in mean arterial blood pressure has been associated with left ventricular hypertrophy.⁶⁰⁰ Findings in adult human studies were nonetheless often confounded by presence of concomitant systemic hypertension.^{601,602} The pressure-dependent parameter such as elastic modulus, but not relatively pressure-independent stiffness index, has been shown to be associated with left ventricular hypertrophy.⁶⁰² Likewise, in an otherwise healthy population of adults, measures of arterial function including elastic modulus, distensibility, and pulse wave velocity have been shown to be significant determinants of left ventricular mass when blood pressure is removed from the statistical model.⁶⁰¹

Arterial stiffening is associated with alteration of phasic coronary flow pattern.^{598,603} Early return of the reflected pressure wave augments the systolic pressure and lowers the diastolic coronary perfusion pressure. In a canine model with aortic bypass by a stiff conduit, the percentage of systolic coronary flow was found to increase from a normal of 25% to almost 50%.⁶⁰³ The tighter coupling of coronary perfusion to systolic pressure has important implications. As the ventricular systolic performance and pressure declines due to causes such as acute ischaemia,

the fall in systolic pressure would have more pronounced effects than expected on the size of the ischaemic bed and ventricular function due to a shift to greater reliance on systolic coronary perfusion.⁶⁰⁴

The afterload dependence of cardiac relaxation is well recognised.^{605–607} While the mechanisms remain elusive, recent evidence suggests a potential role of troponin I phosphorylation.⁶⁰⁸ Additionally, the increased myocardial oxygen consumption, left ventricular hypertrophy, and decreased diastolic coronary perfusion pressure secondary to arterial stiffening predispose to subendocardial ischaemia and interstitial fibrosis, which in turn can impair myocardial relaxation and reduce ventricular compliance.^{609,610} Indeed, the associations between arterial stiffness and left ventricular diastolic dysfunction in adults with hypertension^{610–613} and diabetes mellitus^{611,613,614} are well recognised. The association between arterial stiffening and left ventricular systolic function has also been reported. In adults with⁶¹⁵ and without⁶¹¹ coronary artery disease, aortic and conduit arterial stiffness has also been inversely related to long-axis systolic left ventricular function. In adults with coronary artery disease, an inverse relationship between brachial-ankle pulse wave velocity and left ventricular ejection fraction has been reported.⁶¹⁵ Nonetheless, maintenance of systolic function in the presence of increased afterload may be achieved through adaptive left ventricular hypertrophy, shift of myocardial myosin heavy chain from α - to β -isoform that develops a slower, more energy efficient term of contraction,⁶⁰⁰ facilitation of transduction of cardiomyocyte contraction into myocardial force development by the fibrillar collagen, and the Anrep effect.

Effect of Ventricular Dysfunction on Systemic Circulation

Systemic ventricular dysfunction with development of heart failure is associated with sympathoadrenal activation, activation of the renin-angiotensin system, systemic inflammation, and increased oxidative stress.^{616,617} While left ventricular dysfunction occurs most commonly in acquired conditions such as ischaemic heart disease and dilated cardiomyopathy, the syndrome of heart failure in the context of systemic ventricular dysfunction complicating congenital heart lesions is increasingly recognised.^{618,619}

Arterial dysfunction in adults with chronic heart failure is well documented. Despite reduced brachial arterial diameter in these patients, increased brachioradial arterial pulse wave velocity has been reported.⁶²⁰ Reduced radial, carotid, and aortic distensibility, as determined by echotracking, has also been shown.⁶²¹ Progressive arterial stiffening is found in adults with worsening New York Heart Association functional class.⁶²⁰ Furthermore, in adults with heart failure, reduced endothelial-dependent increase in forearm blood flow^{622–624} and dilation of femoral arteries⁶²⁵ have been demonstrated.

Several mechanisms may account for systemic arterial dysfunction in heart failure. Contraction of vascular smooth muscle secondary to activation of the sympathoadrenal and renin-angiotensin systems modulates arterial stiffness through increasing vascular tone. In a canine model of heart failure, decreased gene expressions of endothelial nitric oxide synthase and cyclooxygenase-1 have been found, suggesting reduction of release of

endothelium-derived vasodilating substances.⁶²⁶ Whether basal nitric oxide production is reduced or increased in heart failure is, however, controversial.⁶²⁷ Nonetheless, direct evidence suggests decreased synthetic activity of the L-arginine-nitric oxide pathway.⁶²⁸ Using isotope-labeled L-arginine to assess synthesis of nitric oxide, urinary excretion of isotope-labeled nitrate was found to be reduced in patients with heart failure at rest and during submaximal exercise. Increased degradation of nitric oxide can also occur in heart failure due to its inactivation by reactive oxygen species.⁶²⁹ Increased angiotensin-converting enzyme activity in heart failure increases breakdown of kinins, which in turn may lead to reduction of nitric oxide release.⁶³⁰

Apart from activation of the neurohumoral system and reduced availability of endothelium-derived vasodilating substances, elevation of endothelium-derived vasoconstrictors, in particular endothelin, in congestive heart failure may also contribute to increased vascular tone and arterial stiffening.⁶³¹ Indeed, endothelin-1, the major isoform in the cardiovascular system, is elevated in adults with heart failure and related to severity of haemodynamic disturbance and symptoms.^{632–634}

The elevation of circulating proinflammatory cytokine tumor necrosis factor- α in heart failure⁶³⁵ may also contribute to arterial dysfunction. Administration of tumor necrosis factor- α has been shown to reduce acetylcholine-induced vascular relaxation in a rat model.⁶³⁶ Possible mechanisms include increased production of reactive oxygen species, blockage of activation of endothelial nitric oxide synthase, and direct degradation of endothelial nitric oxide messenger RNA.^{637–638} Importantly, tumor necrosis factor- α antagonism with etanercept in adult patients with advanced heart failure has been shown to improve the impaired systemic endothelial vasodilator capacity.⁶³⁷

Ventriculo-arterial Coupling

It is obvious from the above discussions that reciprocal interactions between the arterial system and systemic ventricle, if unfavorable, may set up a vicious cycle (Fig. 6-12). Interactions between the left ventricle and the systemic circulation have been studied under frameworks of ventriculo-arterial coupling.^{639–642} Analysis of the forward- and backward-traveling wave energy has also been used to assess ventriculo-arterial interaction.^{643,644} By far, the framework proposed by Sunagawa et al has been used most commonly for analysis of ventriculo-arterial coupling in humans in health and disease.⁶³⁹ In this framework of ventriculo-arterial coupling, the systemic ventricle and the arterial system are considered as two elastic chambers (Fig. 6-13). The volume of blood transferred from one chamber to the other is determined by their relative elastance, expressed as the ratio of effective arterial elastance (E_a) to ventricular end-systolic elastance (E_{es}). In this model, the coupling is studied in terms of the pressure-volume relationship (Fig. 6-14).

Effective arterial elastance is defined as the ratio of end-systolic pressure to stroke volume and is used as an index of total external load opposing left ventricular ejection. Arterial elastance takes into account of both the static and pulsatile components of the arterial load, as it depends on the total peripheral resistance, total arterial compliance, and

Figure 6-12 Unfavorable interactions in the presence of arterial dysfunction between the systemic circulation and left ventricle. The setting up of vicious cycles (dashed lines) may aggravate pre-existing arterial and ventricular dysfunction.

Figure 6-13 Venticuloarterial coupling model. The systemic arterial system and systemic ventricle are considered as elastic chambers with volume elastance E_a and E_{es} , respectively. The stroke volume (SV) being transferred from the heart to the arterial system when the two are connected is determined by their relative elastance. (Adapted with modification from Sunagawa K, Maughan WL, Burkhoff D, Sagawa K: Left ventricular interaction with arterial load studied in isolated canine ventricle. *Am J Physiol* 1983;245: H773–H780.)

Figure 6-14 Ventriculo-arterial coupling framework based on pressure-volume relations. Left ventricular end-systolic elastance (E_{es}) is represented by the end-systolic pressure volume relationship, which can be obtained from pressure-volume loops generated at varying loads. V_0 is the volume axis intercept of the end-systolic pressure volume relationship. Arterial elastance (E_a) equals the ratio of end-systolic pressure to stroke volume. The equilibrium point at which the ventricle is coupled with the arterial system lies at the intersection with a common peak end-systolic pressure.

aortic characteristic impedance. While the contribution of total peripheral vascular resistance and cardiac frequency to arterial elastance is greater than arterial stiffness,^{639,645} arterial elastance has been shown to reflect pure alterations in arterial compliance, wave reflection, and characteristic impedance.⁵⁹⁹ Importantly, the fact that arterial elastance is expressed in terms of pressure-volume relationship enables its coupling to the elastance of the left ventricle.⁶⁴⁶

The left ventricular elastance is represented by the slope of end-systolic pressure-volume relationship, determined from a family of pressure-volume loops and commonly regarded as a load-independent index of contractility. The intersection of the arterial end-systolic pressure-volume relationship and ventricular end-systolic pressure-volume relationship represents the equilibrium end-systolic pressure and volume where the two systems couple. The effective stroke volume being transferred can be calculated by the formula stroke volume = (end-diastolic volume – V_0) / (1 + E_a/E_{es}), where V_0 is the volume axis intercept of the end-systolic pressure-volume relationship.⁶³⁹ It is worthwhile to note that both arterial elastance and ventricular elastance vary dynamically during the cardiac cycle and reach a maximum at end-systole.

The coupling ratio, E_a/E_{es} , has been used extensively in humans for characterisation of interaction between the systemic ventricle and arterial system.^{599,647,648} Analytical modeling in isolated canine hearts has shown that the left ventricle delivers maximal stroke work when E_a/E_{es} approaches 1, while the mechanical efficiency of the ventricle, defined as the ratio of stroke work to myocardial oxygen consumption, is maximal when the ratio is about 0.5.⁶⁴⁹ In normal humans, the ratio has been shown to lie between 0.7 and 1.0.^{648,650} In isolated canine hearts, it has further been shown that over an E_a/E_{es} ratio spanning 0.3

and 1.3, the left ventricular stroke work and cardiac efficiency remain nearly optimal, whereas both decline at higher and lower ratios.⁶⁵¹ This framework of ventriculo-arterial coupling has been used commonly to analyse interactions between the arterial system and the systemic ventricle in children with congenital and acquired heart disease.

Relevance in Congenital and Acquired Heart Disease in the Young

Fontan Physiology

The Fontan physiology is characterised by connection in series of the systemic and pulmonary circulation. Theoretical modeling using the ventriculo-arterial coupling framework suggested increased arterial elastance, reduced ventricular end-systolic elastance, increased E_a/E_{es} ratio, and reduced ventricular external stroke work and mechanical efficiency.⁶⁵² In clinical studies, elevated systemic^{653,654} and total vascular resistance⁶⁵⁵ has been demonstrated consistently. The pulsatile component of the afterload, as determined from the first harmonic impedance in the impedance spectra, has also been shown to be elevated in Fontan patients.⁶⁵⁵ Importantly, the first harmonic impedance was found to correlate negatively with cardiac index. In a canine model of Fontan circulation, the input impedance at zero harmonic and characteristic impedance were also found to be elevated.⁶⁵⁶ The cause of increased pulsatile afterload in Fontan circulation is not entirely clear. Proposed explanations include increased wave reflections⁶⁵⁵ and sympathetic activation as a compensatory mechanism for reduced cardiac output.⁶⁵⁶ Documented endothelial dysfunction in these patients might also play a role through modulation of vascular tone.^{657,511}

In terms of ventriculo-arterial coupling, Fontan patients have been found to have increased arterial elastance without concomitant changes in ventricular end-systolic elastance, indicating that abnormal coupling is due to increased afterload.⁶⁵⁸ In this study, the coupling E_a/E_{es} ratio in Fontan patients was found to be around 1.5, and the reduced cardiac index at baseline was attributed to increased afterload rather than decreased ventricular contractility. Compared with biventricular circulation, Fontan circulation is found to be associated with reduced ventricular hydraulic power and higher ventricular power expenditure per unit cardiac output.⁶⁵⁵

Interestingly, staged total cavopulmonary connection with a preceding bidirectional Glenn procedure has been demonstrated to be associated with a smaller increment in arterial elastance after surgery and reduced E_a/E_{es} ratio, as compared to increased E_a/E_{es} ratio after primary total cavopulmonary connection.⁶⁵⁹

Given the findings of abnormal ventriculo-arterial coupling in Fontan physiology, the use of afterload-reducing agents should theoretically improve haemodynamics and coupling. Nonetheless, administration of enalapril for 10 weeks in a small cohort of Fontan patients was found not to alter systemic vascular resistance, resting cardiac index, and exercise capacity.⁶⁶⁰ It is important to realise, however, that limited β -adrenergic reserve in Fontan patients induced by dobutamine^{655,658} is primarily related to a limited preload, which could have been further reduced after enalapril. Further studies are required to clarify the controversial role of systemic vasodilators in optimizing the Fontan haemodynamics.

Norwood Procedure

The ventriculo-arterial coupling ratio in patients after a Norwood procedure with a right ventricular-pulmonary artery conduit has been shown to be similar to those with a systemic-pulmonary shunt.⁶⁶¹ This holds true even after a bidirectional Glenn procedure and total cavopulmonary connection. However, ventricular end-systolic elastance was found to be lower in the right ventricular-pulmonary artery conduit group after bidirectional Glenn procedure and total cavopulmonary connection. This has been attributed to deleterious influence of ventriculotomy on systemic right ventricular function. Afterload reduction for the lowering of arterial elastance and optimisation of coupling ratio is thought to be beneficial.

Systemic Left Ventricle in Biventricular Circulation

In a porcine model of paediatric cardiopulmonary bypass, arterial elastance was found to be increased while ventricular end-systolic elastance was found to remain unchanged.⁶⁶² The absence of compensatory increase in ventricular contractility provided an explanation for the low cardiac output syndrome in this cardiopulmonary bypass model. Importantly, this study demonstrated that milrinone or levosimendan prevented the increase in arterial elastance after bypass, probably through their systemic vasodilator properties, and protected against the reduction in cardiac output. These findings shed light on the understanding of the beneficial effects of prophylactic milrinone in the prevention of low cardiac output syndrome in infants and young children after open heart surgery.⁶⁶³

In children with coarctation of the aorta, the increased afterload is characterised by increased arterial elastance.⁶⁶⁴ Interestingly, data suggested that clinical symptoms of heart failure are related to left ventricular contractile response to increased afterload. Increased ventricular end-systolic elastance that matches with increased arterial elastance was characteristic of asymptomatic patients, while infants with overt heart failure were found to have minimal increase in ventricular end-systolic elastance consistent with afterload mismatch. In an animal model of aortic coarctation, banding of the aortic arch has been shown to increase aortic characteristic impedance and cause concentric left ventricular hypertrophy.⁶⁶⁵ In adolescents after successful repair of coarctation, increased stiffness of the ascending aorta has been found to correlate with the degree of impairment of left ventricular longitudinal strain rate.⁶⁶⁶

The response of the systemic circulation to systemic ventricular dysfunction has been alluded to earlier. Indeed, studies have shown suboptimal ventriculo-arterial coupling in adults with idiopathic non-ischaemic cardiomyopathy.^{667,668} The arterial elastance was found to be elevated, which has been attributed to increased systemic vascular resistance, tachycardia, and decreased stroke volume.⁶⁶⁸ As expected, with reduced cardiac contractility, ventricular end-systolic elastance was found to be decreased in these patients.⁶⁶⁹ Although inotropes have been shown to improve the coupling, their effects on mechanical efficiency were found to be minimal.⁶⁶⁷

In adolescents and adults with β -thalassaemia major, arterial elastance has been shown to be elevated and to correlate positively with total vascular resistance and negatively with systemic vascular compliance.⁵⁵¹ Increased arterial elastance is probably related to arterial stiffening and endothelial dysfunction in these patients.⁵⁴⁷ Importantly, arterial

elastance was also found to be a significant negative determinant of cardiac contractility. Afterload reduction with oral enalapril has been shown to improve systolic and diastolic function in asymptomatic or minimally symptomatic thalassaemia patients with left ventricular dysfunction.⁶⁷⁰

Interactions between systemic arterial load and left ventricular structure and function have also been shown in adolescents and young adults with paediatric-onset systemic lupus erythematosus.⁵²⁸ Carotid arterial stiffness, being increased in these patients, was found to be a significant independent determinant of mass, myocardial performance index, and relatively load independent indices of systolic and diastolic function of the left ventricle.

Systemic Right Ventricle in Biventricular Circulation

In asymptomatic adolescent and adult survivors of the Mustard operation, increased E_a/E_{es} ratio with a mean of 3.47 has been reported.⁶⁷¹ Increased arterial stiffness^{493,496} might in part account for the suboptimal ventriculo-arterial coupling. Enhancement of systemic right ventricular contractility by dobutamine has been shown to reduce the ratio to approach unity, which suggests improved coupling.⁶⁷¹ Disappointingly, administration of afterload-reducing agents including enalapril⁶⁷² and losartan⁶⁷³ did not improve exercise capacity in patients with transposition of the great arteries after atrial switch operation. Possible causes include minimal baseline activation of the renin-angiotensin system⁶⁷³ and limited preload due to impairment of atrioventricular transport.^{671,674}

THE FUTURE

A comprehensive understanding of the normal functioning of the systemic circulation requires its appraisal from the structural, physiological, and mechanical perspectives. Over the last decade, there has been an increasing interest in the role of systemic arterial dysfunction as a risk factor and a probable etiologic factor for cardiovascular disease in adults. Concurrent development of non-invasive methodologies for assessment of systemic arterial function, notably arterial stiffness and endothelial function, leads to its increasing utilisation in the paediatric population. The list of childhood conditions associated with arterial dysfunction has since expanded rapidly. Further studies to elucidate the underlying mechanisms of arterial dysfunction in the young are undoubtedly warranted. Additionally, longitudinal studies are required to clarify whether systemic arterial dysfunction tracks from childhood to adulthood and whether arterial dysfunction detected early in life would have an impact on cardiovascular health in the long term. Although strategies to reduce arterial stiffness and to improve endothelial dysfunction have been proposed and their potential benefits demonstrated in selected high-risk cohorts of paediatric patients, their benefits in otherwise healthy children remain unknown. Advances in molecular biology would further unveil the genetic determinants of vascular structure and function, which may provide novel targets for reversal of arterial dysfunction. It cannot be overemphasised that optimal interaction between the systemic circulation and the systemic ventricle is instrumental in ensuring the normal functioning of the cardiovascular system. Further understanding of ventriculo-arterial coupling

in paediatric cardiac conditions, in particular congenital heart disease associated with systemic ventricular dysfunction, would shed light on the choice of the most appropriate management strategy.

This review summarises the frameworks of ventriculo-arterial coupling, examines assumptions, and provides insight in their clinical applications. It provides the basis for the application of coupling frameworks in the study of ventriculo-vascular interactions in the various congenital and acquired heart conditions as discussed at length in this chapter.

Pulmonary Circulation

SHEILA G. HAWORTH and MARLENE RABINOVITCH

Understanding the features of the pulmonary circulation is critically important in the management of patients with congenitally malformed hearts. The past 10 years have seen remarkable advances in our understanding of its development, the genetics, pathobiology, and treatment of pulmonary vascular disease, and the physiology of this circulation. Primary intracardiac repair in infancy has become the norm, but the selection of patients suitable for intracardiac repair can still pose a problem, particularly in developing countries when many patients present late. Assessment has been facilitated by improvements in tissue Doppler imaging, computerised tomography, and magnetic resonance imaging. The patients who, in the absence of surgical correction, develop the Eisenmenger syndrome and become severely symptomatic can be helped by treatment with new medicines used to treat idiopathic pulmonary hypertension. Advances in our understanding of the pathogenesis of pulmonary vascular disease now influence our approach to the management of many patients with congenitally malformed hearts and pulmonary hypertension. In this chapter, we will focus on the normal and abnormal development of the pulmonary circulation, neonatal circulation, the hypoperfused lung, and advances made in the pathobiology and treatment of pulmonary vascular disease.

NORMAL PULMONARY CIRCULATION

Normal Anatomy of the Pulmonary Circulation

The functional unit of the lung is the acinus. An acinus is all the lung tissue supplied by a terminal bronchiolus. In the mature lung, it includes up to eight generations of respiratory bronchioluses, alveolar ducts, and the alveoluses beyond (Fig. 7-1). It is the respiratory unit of the lung. At the end of any airway, three to five acinuses are grouped to form a lobule. Each small airway is accompanied by a branch of the pulmonary artery until the arteries finally enter the capillary network of the alveolar walls. The acinuses and lobules, with their accompanying arteries, are the last part of the lung to appear before birth. It is these structures that are remodelled in the normal lung with growth, and which change most readily in disease. The bronchopulmonary segment is the basic topographical unit of the lung. It is a wedge of lung tissue supplied by a principal branch of a lobar bronchus and its accompanying pulmonary artery. The pulmonary veins and lymphatics lie in the intersegmental plane, receiving tributaries from adjacent segments.

The bronchopulmonary segment is the surgical unit of lung tissue, since a segment can be resected along its intersegmental boundaries. Familiarity with normal bronchopulmonary segmental anatomy also helps the cardiologist because,

when examining pulmonary angiograms, he or she must ensure that all the bronchopulmonary segments are normally connected to the intrapericardial pulmonary arteries. Segments that are not perfused by a normal pulmonary arterial supply must be identified, and a search made for their source of systemic arterial supply. On angiography, large collateral systemic arteries arising from the aorta, often called major aortopulmonary collateral arteries, are distinguished from large bronchial arteries by their origin, distribution, and proximal connections with the hilar, lobar, or segmental arteries. The final destination of bronchial arteries is not seen angiographically, since the majority of them connect with the intra-acinar pulmonary arteries.

Bronchial Circulation

In children with congenitally malformed hearts, the bronchial circulation may provide an alternative source of arterial supply to the pulmonary capillaries when there

Figure 7-1 Diagram of the airway and arterial pathway, showing an elastic artery that accompanies cartilaginous lobar, segmental and subsegmental bronchi. The pulmonary artery becomes muscularised at the 7th to 9th division from the segmental hilum (asterisk). AD, alveolar duct; RB, respiratory bronchiolus; TB, terminal bronchiolus.

is little or no flow of blood down the lobar or segmental arteries. In the presence of obstructed or absent pulmonary veins, the bronchial veins drain oxygenated blood from the lung into the systemic veins.

The main bronchial arterial supply usually arises from the aorta directly, or from an intermediary intercosto-bronchial artery. The number of vessels arising from the aorta to supply each lung varies in the normal circulation. The most common anatomical patterns seen in one series included two posterior bronchial arteries supplying each lung in about one-third, two arteries supplying the left and one the right lung in one-fifth, with this relationship mirror-imaged in a further sixth, and a single trunk supplying each bronchus in a further tenth.¹ The successive branches of each bronchial artery are described as superior, middle, and inferior, this reference made to the relative levels of origin from the aorta, and not the ultimate level of distribution within the lung.

Additional accessory bronchial arteries may arise from the subclavian, brachiocephalic, or internal thoracic arteries. When the bronchial arterial circulation is expanded to provide an alternative source of blood supply to the lung, these and other vessels enlarge, distributing blood through the bronchial arteries via the pulmonary ligaments and retroperitoneal tissues. Blood is also distributed from the pericardiophrenic, oesophageal, and other mediastinal vessels, and occasionally from a coronary artery. Within the lung, each lobar and segmental bronchus is accompanied by two large bronchial arteries, which frequently anastomose around the bronchus.

Microscopically, the bronchial arteries are readily distinguishable from the pulmonary arteries by their position in the lung and by their mural structure. They accompany the bronchuses to supply the adventitial and mucosal layers, along with the walls of large pulmonary arteries. They lie next to the bronchial veins and the nerves that supply the large airways. As in other systemic arteries, the medial wall is thick and muscular, the internal elastic lamina is well defined, and the external elastic lamina is interrupted or absent. The structure of bronchial arteries frequently changes with age in the normal lung. Longitudinal muscle bundles develop, which may even occlude the lumen. The mechanism for this change is not understood.

There are two types of bronchial veins: the deep and the superficial, or pleurohilar, veins. Both types communicate freely with the pulmonary veins. The deep veins originate in the walls of the terminal bronchioluses, and eventually drain into the left atrium directly or via the pulmonary veins. The pleurohilar veins from the right lung drain into the azygos vein, while those from the left lung drain into the hemiazygos, superior intercostal, or brachiocephalic veins. Microscopically, a bronchial vein has a thinner wall than a pulmonary vein for a given diameter. Unlike pulmonary veins, bronchial veins contain delicate bifoliate valves, which are more commonly seen in the immature than in the mature lung.

Microscopic Assessment of the Pulmonary Arteries and Veins

In the normal child, the lung is remodelled with growth. In the abnormal lung, therefore, each structural feature must be compared with that of age-matched controls in tissues prepared and analysed in the same manner. To make such a comparison, the intrapulmonary arteries must be

identified. They cannot be identified according to their size, because this changes in the normal lung with age, and may also change in disease. In a postmortem specimen, the elastic and large muscular arteries are identified by counting the number of generations that separate them from the segmental hilum, counting the segmental artery as the first generation. Their mural structure is determined by their position in the lung. Within the acinus, arteries continue to branch with the airways. On microscopic examination of both biopsy and postmortem tissue, the arteries are identified according to the type of airway they accompany, that is, terminal or respiratory bronchioluses, alveolar ducts, or ones that lie within the alveolar walls (see Fig. 7-1). Describing any part of the pathway in terms of arterioles is best avoided, because this term is open to different interpretations based on size, structure, and function, or a combination of attributes. In a large and unselected population of arteries, the mean percentage medial thickness can be calculated from measurements of medial thickness and external diameter. Other assessments include the mean ratio of arterial lumen to wall, the area of muscle present, and an index of medial muscular tissue present in the lung. Population counts reveal the relationship between mural structure, size, and the position in the arterial pathway. Arterial muscularity is usually assessed by determination of percentage medial thickness, and by finding the extent to which muscle has differentiated along the arterial pathway as judged both by the size and the position of the artery in the lung field. The number of arteries per unit area, or volume, of lung can be determined and the ratio of alveoluses to arteries calculated to overcome any difference in the degree of inflation in different lungs. In postmortem specimens, the effect of hypoperfusion on lung growth can be studied by determining the number and size of alveoluses. The veins are studied in a comparable manner.

Anastomoses Between Pulmonary and Bronchial Circulations

In the normal adult, most of the proximal connections between the pulmonary and bronchial arteries accompanying the same airway occur at the level of non-cartilaginous bronchioluses. More peripherally, the small bronchial arteries become indistinguishable as they anastomose with small pulmonary arteries around the necks of respiratory and terminal bronchioluses. In addition, branches of the bronchial arteries that accompany large and small airways anastomose with adjacent thin-walled pulmonary arteries in the surrounding lung tissue. These connections are called bronchopulmonary arteries. They are relatively common in the normal fetal and neonatal lung. Subepithelial bronchial arteries also anastomose with small precapillary pulmonary arteries.

The frequency with which the bronchial and pulmonary arterial circulations anastomose explains why accidental surgical interruption of a pulmonary artery, or ligation of a collateral artery providing the only source of blood supply to a region of lung, does not usually lead to infarction of the lung. By contrast, experimental stripping of the bronchial arteries at the hilum leads to necrosis of the bronchial wall near the hilum. In the venous circulation, there are many connections between bronchial and pulmonary veins. These enlarge in the presence of pulmonary venous hypertension. Blood may then flow from the pulmonary veins

indirectly to the right atrium. Arterio-venous connections are not found in the normal lung.

Pulmonary Lymphatics

The superficial lymphatic network lies in the pleura, and the deep network lies in the interstitium. The two networks anastomose around the hilum, and drain to the hilar and tracheobronchial lymph nodes. Lymphatics are present in the pleura, in connective tissue septums, around the pulmonary arteries and veins, and in the bronchial wall, including the mucosa. Microscopically, small lymphatics consist of endothelial cells lying on a basement membrane, while in the large channels the walls are strengthened by the addition of collagen and elastic fibres, and an occasional muscle cell. The lymphatics contain delicate bicuspid valves. When pulmonary venous return is obstructed, either at the mitral valve or within the pulmonary veins themselves, the lymphatics become dilated. In the presence of long-standing obstruction, the walls of the lymphatics may be thickened by an increase in the amount of smooth muscle.

Biopsy of the Lung

A biopsy should be taken from the inflated lung. It is fixed in inflation to ensure distention of the airways, and hence their identification. The biopsy will be representative of the entire vasculature in a young child, providing that the flow of blood is evenly distributed. The lingula is best avoided, since even in the normal lung the arteries of this region tend to be more thick walled. In adults with rheumatic mitral stenosis, the lower lobe vessels are usually more severely affected than the rest of the vasculature. In any biopsy, the mural structure of the pulmonary arteries varies, as is to be expected, since the pulmonary arterial tree is a branching system. All arteries at a certain point along the pathway, in both normal and abnormal lungs, are structurally similar to, and different from, arteries proximal and distant to them.

Morphologic Assessment of Right Ventricular Hypertrophy

In the normal heart, the septum is considered as part of the left ventricle. Hypertrophy of the right ventricle, therefore, is indicated by a decrease in the ratio of the weight of the left ventricle and the septum assessed relative to the weight of the right ventricle. During fetal life, the right ventricle forms a greater proportion of the total ventricular weight than it does in the child or adult. At sea level, the ratio of between 2.3 to 1 and 3.3 to 1, as expected in the adult, is normally achieved when the infant reaches 4 months of age.²

DEVELOPMENT OF THE HUMAN PULMONARY VASCULATURE

Structural Development

Morphological study of the development of the pulmonary vasculature in the human describes the creative process, and provides clues about regulatory mechanisms which can be explored in other species and in experimental models. Abnormal development is informative in that it can be viewed as a vicarious experiment.

The heart tube is formed by the end of the third week of gestation, and about 5 days later the lung bud develops at the caudal end of the laryngotracheal groove. The lung bud expands laterally and divides into the two primordial lung sacs, each of which then divides first into lobes, and then into bronchopulmonary segments. In the normal lung, recent work shows that the pre-acinar arteries and post-acinar veins form by vasculogenesis from the splanchnopleural mesoderm of the lung bud.^{3,4} The pre-acinar airways and post-acinar veins form in a centrifugal manner from hilum to periphery, but the vessels do not.^{3,4} They form by continuous coalescence of endothelial tubes alongside the newly formed airways, which appear to provide a template for pre-acinar arterial development (Fig. 7-2). The continuous addition of endothelial tubes gradually lengthens the pulmonary arteries and veins. The heart is connected to the two lung buds from a very early stage of embryonic life. By at least 34 days of gestation, serial reconstructions demonstrate physical continuity between the aortic sac, the pulmonary arteries, the peribronchial capillary plexus, the pulmonary veins, and the atrial component of the heart. Thus, blood can circulate through the lung earlier than had been supposed, exposing the developing structures to circulating factors generated at distant sites, including angioblasts and other cells which could become incorporated into the vessel wall. The extent to which angiogenesis contributes to formation of vessels during this pseudoglandular phase is uncertain, but it may be responsible for the supernumerary vessels. Angiogenesis predominates later, and is thought to be responsible for formation of intra-acinar arteries, which starts in the canalicular phase with further development of airways and alveoluses, and continues after birth. All the pre-acinar arteries and airways have formed by the 16th week of gestation. Between a third to a half of the adult complement of alveoluses and intra-acinar arteries form before birth, with new structures then forming most rapidly within the first 6 months of life. After 3 years of age, development mainly consists of an increase in size of existing structures.

The pulmonary arterial smooth muscle cells are derived from three sites in a temporally distinct sequence³ (Fig. 7-3). The first cells to surround the endothelial tubes migrate from the bronchial smooth muscle around the neck of each terminal bud. These cells become surrounded by the second population, which differentiates from mesenchymal cells. The third source is from endothelial cells in the most peripheral arteries, which transdifferentiate into smooth muscle cells later in gestation, from 98 to 140 days. Venous smooth muscle does not derive a contribution from bronchial smooth muscle.⁴ Irrespective of their origin, all smooth muscle cells follow the same sequence of expression of smooth muscle specific cytoskeletal proteins. Maturation takes place from the subendothelium to the adventitial layers, and from hilum to periphery. In the pulmonary veins, the cytoskeletal proteins appear in the same sequence as in the pulmonary arteries, but do not express caldesmon, which might help explain why pulmonary veins are so responsive to contractile agonists.

The lymphatics originate at the hilum, and are first seen at about 56 days of gestation.³ By the end of the pseudoglandular period, lymphatic channels have subdivided the lung periphery, positioned in the prospective connective tissue septums. The bronchial arteries develop from the dorsal aorta relatively late in gestation, at about 8 weeks

Figure 7-2 **A**, Drawing derived from a serial reconstruction of the human embryo viewed from the left side of the left lung at 38 days of gestation. Peripheral capillaries are clustered around each terminal bud. A mesenchymal sheath surrounds the lung bud and vessels, continuous with that of the trachea and oesophagus. LB, left bronchus; LPA and RPA, left and right pulmonary arteries; SV, sinus venosus. **B**, Microscopic transverse section of human lung at 56 days of gestation, stained for alpha smooth muscle actin, showing terminal buds (TB) and adjacent coalescing endothelial tubes joining the newly formed pulmonary artery proximally (*asterisk*).

Figure 7-3 Origins of pulmonary arterial smooth muscle (SM). Tissue stained with alpha smooth muscle actin. **A**, Mesenchymal cells, as yet containing no cytoskeletal markers, aligning around first layers of muscle cells. **B**, Bronchial smooth muscle surrounding adjacent endothelial tubes. **C**, Endothelial cells undergoing transdifferentiation. of gestation. When flow through the extrapulmonary arteries is abnormally diminished in late fetal life, or after birth, the bronchial arteries enlarge to supply the peripheral pulmonary arteries through connections between the pulmonary and bronchial circulations. Many such connections exist in the normal fetus and newborn, suggesting great adaptability, but they appear to decrease rapidly in size and number after birth. The structure of the pulmonary trunk reflects the high pulmonary vascular resistance of fetal life.

It has a similar mural structure to that of the aorta, having concentric, compact parallel elastic fibres of uniform thickness.

Growth and Innervation after Birth

As the intrapulmonary arteries increase in size, their walls thicken to maintain a constant low relationship to the external diameter. In the arteries of the respiratory unit, smooth muscle cells differentiate from precursor

intermediate cells and pericytes already in position, and as judged by light microscopy, non-muscular arteries become partially or completely muscularised. Muscle is said to have extended along the arterial pathway. The elastic laminae in the pulmonary trunk gradually become fragmented, and lose their ordered appearance. The wall of the pulmonary trunk becomes thinner relative to that of the aorta, with a ratio decreasing from unity to a mean value of 0.6 at about 8 months of age.⁵ This ratio is maintained throughout life. The pulmonary vasculature is densely innervated at birth, and becomes more densely innervated with age.⁶ In babies, as in adults, the nerves are predominantly of the sympathetic type. In pulmonary hypertensive infants, the abnormally thick-walled blood vessels are prematurely innervated by 3 months of age.⁶

Regulation of Pulmonary Vascular Development

The presence of a circulation through the pulmonary vasculature from early embryonic and fetal life means that the circulation is exposed to external, distal influences from an early stage in its development. Circulating cells could contribute to building the vessel walls. Angioblasts can stream to developing organ beds from a considerable distance,⁷ and incorporation of marrow-derived stem cells seems likely. The extent to which such cells retain their genetic memory, and the extent to which they can be modified by environmental factors, is of fundamental importance.

The innermost medial smooth muscle cells originate by migrating from bronchial smooth muscle. They have a migratory phenotype in the setting of obstructive pulmonary vascular disease. With respect to cytoskeletal composition, regulation of the actin cytoskeleton by RhoGTPases, and contractility, the smooth muscle cells from the inner and outer medial layers retain stable phenotypic differences when cultured.^{8,9}

These and other observations suggest that the cells may have been recruited into the vessel walls from afar. Because of this, they retain distinct heritable characteristics which would enhance the heterogeneity of the vessel wall, and its potential for adaptation to environmental change.¹⁰ The factors which determine whether an endothelial cell lying in the mesenchyme will become dedicated to either an arterial or a venous system are not understood. The tyrosine receptor EphB4, and its cognate ligand ephrin B2, discriminate between arteries and veins in the mouse, but less so in humans. Early angioblasts commit to either an arterial or a venous fate directed by a Notch gridlock signalling pathway.¹¹ It is possible, however, that pulmonary endothelial cells do not become committed until they have coalesced with an adjacent pulmonary artery or vein. It is at that time that the direction of flow, pressure, and circulating factors might influence commitment.

Experimental and gene targeting studies continue to emphasise the critical role of growth factors in lung development. Each appears to have a precise spatial and temporal expression pattern. In the human lung, we found eNOS, VEGF, and the VEGF receptors Flk-1 and Flt-1 and Tie-2, expressed in the capillary plexus at 38 days.³ eNOS stimulates endothelial proliferation, migration, and formation of tubes, is a downstream mediator of growth factor-induced angiogenesis, and inhibits apoptosis. It is expressed on the endothelium of human arteries, capillaries, and veins

throughout development. VEGF mediates vasculogenesis and angiogenesis. VEGF-A is required for vascular development throughout the embryo, and blood vessels do not form in mice deficient in the VEGF receptor Flk-1.^{12,13} In cultured mouse lungs, VEGF is found at the branching points of peripheral airways. Grafting of beads coated with VEGF increases the density of the capillary bed.¹⁴

The tyrosine receptor kinase Tie-2, and its ligand angiopoietin, is essential in formation of the capillary networks.¹⁵ Also, endothelial phosphorylation of the Tie-2 receptor by angiopoietin leads to proliferation of smooth muscle cells, perhaps indicating that it has a role in the neomuscularisation of newly formed pulmonary arteries.^{16,17} EGF mRNA and TGF α mRNA are expressed in the mesenchymal cells surrounding airways and alveoluses in the human fetal lung from 12 to 33 weeks of gestation,¹⁸ but the receptors for these ligands were found in the airways and were involved in differentiation. Their direct role in vascular development is uncertain. Insulin-like growth factors I and II, and IGF-IR ligands and mRNA, become apparent at 4 weeks.¹⁹ Anti-IGF-IR neutralising antibody reduced the number of endothelial cells and increased apoptosis of endothelial and mesenchymal cells in human lung explants. IGF-1 also upregulates VEGF, further emphasising the crucial role of this growth factor. A low oxygen tension, as occurs during fetal life, stimulates vascular and airway development. This involves HIF-1 α , which upregulates expression of VEGF, and plays an important role in both vasculogenesis and angiogenesis. Studies on HIF-1 α emphasise the importance of cross-talk between developing arteries and airways to ensure the normal development of both structures.²⁰

Functional Development in Fetal and Neonatal Life

The pulmonary endothelium plays a crucial role in adaptation to extra-uterine life. Its two most important functions are to help reduce pulmonary vascular resistance and to facilitate the clearance of alveolar fluid.²¹

During fetal life, the endothelial cells are squat, have a narrow base on the subendothelium and a low ratio of surface to volume, with considerable overlap of lateral cell borders²² (Fig. 7-4). The small arterial lumen offers a high resistance to flow. Pulmonary vascular resistance is probably kept high during fetal life due to a significant release of vasoconstrictor substances, including endothelin-1 and leucotrienes, and low basal release of vasodilators such as nitric oxide and prostaglandin I₂ in the presence of a low oxygen tension. A mechanically induced increase in pulmonary blood flow, or exposure to vasodilators such as a raised oxygen tension, prostaglandin I₂, and acetylcholine induces only transient vasodilation.²³

Endothelial Permeability

During fetal life, the lung is filled with fluid produced by the alveolar epithelium.²⁴ The liquid is absorbed by the alveolar epithelium at birth. Fetal pulmonary endothelial intercellular junctions are complex and fenestrated, while being tighter and less complex in older babies, indicative of improved barrier function. The higher endothelial permeability in fetal pulmonary vessels is probably due to the combined actions of hypoxia and a high level of circulating endothelin-1, VEGF, and angiotensin II. Endothelin-1 induces endothelial permeability, and its receptor antagonists can prevent capillary leakage.^{25,26}

Figure 7-4 Electron micrographs of transverse sections through small muscular arteries, taken at the same magnification. A, Stillborn. B, At 5 minutes of age.

VEGF, originally identified as a vascular permeability factor, is a potent inducer of plasma extravasation. It is produced in large quantities during fetal development. Angiotensin II may affect endothelial permeability via the release of prostaglandins and VEGF.²⁷ By contrast, an increase in nitric oxide has been shown to prevent endothelial leakage in the lung. The postnatal increase in nitric oxide, and the simultaneous reduction in endothelin, may contribute to tightening of endothelial junctions after birth.²⁸ Rho GTPases play an important role in maintaining endothelial junctional integrity, emphasising the necessity of sustaining a high ratio of Rac1 to RhoA.²⁹

The scaffolding proteins in the endothelial cell membrane may also change at birth, and contribute to the perinatal changes in endothelial barrier function. PECAM-1, also known as CD31, influences transendothelial migration of inflammatory cells, mechanosignal transduction, and angiogenesis.³⁰ Considerable amounts of this agent are expressed on fetal rat endothelial junctions, and expression decreases after birth when the barrier is formed between blood and gases. Caveolin-1 is a component of caveolas, an endothelial scaffolding protein which regulates the assembly of different signalling molecules at the plasma membrane.³¹ Studies on doubly homozygous mice with caveolin-1 knocked out indicates that the protein plays a dual regulatory role in controlling lung microvascular permeability, acting as a structural protein required for formation of caveolas and caveolar transcytosis, and as a tonic inhibitor of eNOS negatively to regulate paracellular permeability.³²

Ensuring the Postnatal Fall in Pulmonary Vascular Resistance

Immediately after birth, the pulmonary arterial smooth muscle undergoes remodelling of the cytoskeletal actin, changing shape and showing an increase in the ratio of surface to volume ratio so as to achieve an increase in luminal

diameter.³³ There is a transient reduction in the content of actin, and disassembly of actin filaments, with an increase in monomeric G-actin. The smooth muscular phenotype is regulated by the transcription factor serum response, which is itself negatively regulated by YY1.³⁴ The brief postnatal reduction in filamentous actin causes YY1 to relocate from cytoplasm to nucleus, thereby inhibiting the expression of differentiation markers, and increasing the activity of cell cycle genes. These changes do not occur in the pulmonary hypertensive state.

The transition to breathing air stimulates several physiological actions, including drainage of fetal lung fluid, rhythmic distension of the lung, and an increase in oxygen tension, all of which contribute to the fall in pulmonary vascular resistance.^{35,36} The pioneering studies of Dawes and colleagues in Oxford in the 1960s on fetal sheep showed that mechanical ventilation reduced pulmonary vascular resistance, and that the response was enhanced when the inspired gas was enriched with oxygen.³⁷ Forty years later, no single factor has yet been identified as being primarily responsible for the initiation of vasodilation at birth. Nor do we know whether the endothelial cell, or the smooth muscle cell, is the prime target. It is probable that the abrupt expansion of the lungs leads to a cascade of events that facilitate the activation of vasodilatory responses, and reduce vasoconstrictor stimuli from the endothelium. The onset of breathing is associated with an increase in circulating bradykinin, and the release of prostaglandin I₂ and nitric oxide.^{38,39} The process is thought to be caused by the sudden increase in flow imposing a sheer stress on the endothelium to promote their release. Although the pathway involving nitric oxide appears to play a crucial role in regulating the vasoreactivity of the transitional circulation, it is not essential. Mice deficient in eNOS survive, and

there is no evidence that either iNOS or nNOS compensates for the absence of eNOS.⁴⁰ Irrespective of the signalling pathway under consideration, it is generally assumed that the pulmonary arteries are solely responsible for the postnatal fall in resistance. This is unlikely, since the pulmonary veins are not passive conduits. Newborn porcine pulmonary veins respond to acetylcholine to a greater extent than do pulmonary arteries.⁴¹

Endothelial heterogeneity is evident even before birth. During embryonic development, the endothelial cells show high plasticity, and undergo constant changes in their expression of proteins to match the requirements of the developing vessel.^{42,43} Heterogeneity is demonstrated in the newborn pulmonary circulation by the relaxant response to bradykinin, in which dependence on prostaglandin, nitric oxide, and a hyperpolarising factor differs in conduit and resistance arteries, and changes with age in each segment.^{44,45} The regulation of these alternative signal transduction pathways in the immature normal and hypertensive pulmonary vasculature has still to be determined. Their tolerance to injury differs.

Role of Specific Mediators

Nitric Oxide

All three isoforms of nitric oxide synthase have been identified in the fetal lung.⁴⁶ Production of nitric oxide is regulated by transcription, post-transcriptional modification, availability of substrate, intracellular localisation, production of superoxides, and availability of co-factors.⁴⁷ Endothelial release is influenced by a variety of factors, including shear stress and tension of oxygen, which change dramatically at birth, and growth factors. The basal release of nitric oxide helps control resistance in the ovine fetal and transitional circulation.⁴⁸ Newborn isolated ovine and porcine conduit arteries and fetal and newborn porcine resistance arteries fail to relax to acetylcholine, the response maturing during the first 2 weeks of life.^{23,44,49,50} By contrast, isolated fetal and newborn porcine pulmonary veins relax well in response to acetylcholine at birth, although like the arteries, the response improves with age.⁴¹ Significant release of nitric oxide has also been demonstrated in newborn ovine pulmonary veins, possibly helping explain the experimental response of sheep to L-NAME, as noted above. A relatively poor receptor-mediated response is perhaps not surprising, given the marked changes occurring in the endothelial cell membrane as the ratio of surface to volume increases at birth. The density of muscarinic receptors increases rapidly immediately after birth, and the subtypes change.⁵¹ But the relatively poor neonatal relaxant response is not restricted to receptor-dependant mechanisms, since the vessels do not relax in response to a calcium ionophore^{49,50} Nor is the relatively poor endothelial-dependant relaxation at birth due to the pulmonary arterial smooth muscles cells being incapable of relaxation. The vessels relax in response to exogenous nitric oxide, although this response also improves significantly during the first 2 to 3 weeks of life.^{49,50} There is no lack of nitric oxide synthase at birth. The expression of both the protein and the gene increases markedly towards term, and increases further to reach a maximum at 2 to 3 days of life. As in the adult, the predominant enzyme present at birth is the constitutive endothelial isoform.

There is no absolute or relative deficiency of the co-factor for nitric oxide synthase, BH₄, at birth.⁵² The efficacy of the

enzyme, however, can be reduced by the action of endogenous inhibitors, primarily asymmetric dimethylarginine, which competes with the substrate L-arginine.⁵³ Levels of this inhibitor are high in amniotic fluid, increase towards term, and remain high in fetal blood. It would be expected to exert a significant tonic inhibitory effect on nitric oxide synthase at such concentrations. The inhibitor is certainly present in the urine of healthy newborn infants, and gradually declines to become undetectable by 5 days of age.⁵⁴ It is metabolised to citrulline by the dimethylarginine dimethylaminohydrolase enzymes, DDAH I and II, both of which are highly expressed in the fetal lung. Each isoform is developmentally regulated, and activity of the second increases rapidly immediately after birth.⁵⁵ Both asymmetric dimethylarginine and dimethylarginine dimethylaminohydrolase could play a significant role in the regulation of the fetal and newborn pulmonary vasculature.

The pulmonary arterial smooth muscle cell being targeted by the endothelium is itself changing rapidly. Basal accumulation of cGMP is high at birth, but falls rapidly to a lower adult level by 3 days of age.⁵⁰ This postnatal fall might be explained by the high expression of phosphodiesterase 5 (PDE5) and its hydrolytic activity found in the newborn rat lung.⁵⁶ Studies on lungs of several species also showed that PDE5 was responsible for a greater proportion of PDE activity during the first week of life than in the adult.^{56,57} Despite the basal accumulation and enhanced accumulation of cyclic GMP in response to nitric oxide and its donors, the relaxation response of newborn vessels is less than might be expected. This might be accounted for by the smooth muscle cell membrane being more depolarised at birth than later.⁵⁸

Prostacyclin

Metabolism of arachidonic acid metabolism within endothelial cells leads to the production of vasoactive eicosanoids, either prostaglandins or leucotrienes. The circulating concentration of vasoconstrictor leucotrienes C₄ and D₄ decreases at birth and that of endothelial-derived prostacyclin increases, facilitating relaxation of the smooth muscle cells. The receptor for prostacyclin belongs to the family of G-protein coupled receptors.⁵⁹ Its effects are mediated by cAMP, though there may also be a cAMP-independent coupling of the receptor to the activation of potassium channels, which are important in the relaxation of smooth muscle cells.⁶⁰ The levels of prostacyclin during early fetal life are low, and this effect may be attributed to the inhibitory action of plasma glucocorticoids on endothelial transcription of the COX-1 gene, and expression of COX via a glucocorticoid receptor.⁶¹ Levels increase at birth, a change coinciding with increasing levels of oestrogen in the fetal plasma. Physiologic levels of estradiol 17 activate synthesis of prostacyclin.⁶² We lack information, however, about the function of the different subtypes of the prostacyclin receptor during development. Whether prostacyclin is crucial to the postnatal reduction in pulmonary arterial pressure is still uncertain. Expression of prostacyclin synthase is low at birth, and increases rapidly in the first week of life. Synthesis is higher in newborn than fetal vessels in the sheep,⁶³ as COX-1 activity is upregulated. The sudden increase in shear stress at birth, and the fall in pulmonary vascular resistance, coincide with the increased release of nitric oxide and prostacyclin, suggesting that the two agents may act in concert to effect the vasodilatory

action of shear stress. Although inhibition of nitric oxide blocks the vasodilation resulting from increased oxygen and rhythmic pulmonary distension, COX inhibitors also attenuate vasodilation caused by rhythmic distension.⁶⁴

Endothelin

The level of circulating endothelin-1 is high in the normal fetus at term, and falls rapidly during the first week of life. Endothelial release of this potent vasoconstrictor is stimulated by hypoxia, the mechanical stimulation of shear stress and stretch, and chemical stimuli such as thrombin, norepinephrine, transforming growth factor- β , phorbol esters, and calcium ionophores. In the presence of high vascular tone, the agent has a vasodilatory effect, but similar infusions have a vasoconstrictor effect when pulmonary vascular tone is decreased during acute ventilation. It generally causes transient vasodilation followed by sustained vasoconstriction. It is abundant in the lung parenchyma and pulmonary arteries at birth, the expression decreasing initially, then increasing again, but at a lower level than in the newborn. Receptor binding sites are densely distributed over the smooth muscle cells of pulmonary vessels, with a relative increase in the B type with age. Between birth and 3 days, vasodilator receptors are transiently expressed on the pulmonary arterial endothelial cells.⁶⁵ This vasodilatory response to endothelin-1 increases after birth in both pulmonary arteries and veins.⁶⁶

Angiotensin

The role of the vasoconstrictor angiotensin in the regulation of the perinatal circulation is not understood. It is first expressed on the endothelium of large proximal pulmonary arteries in the pseudoglandular stage of lung development, and extends distally during gestation.⁶⁷ Expression of angiotensin-converting enzyme is 10 times lower at birth than in the mature rat lung. The vasoconstricting effects of angiotensin are largely due to angiotensin-mediated increases in the production of endothelin-1,⁶⁸ suggesting that its release may decrease immediately after birth.

Failure to Adapt to Extra-uterine Life: Persistent Pulmonary Hypertension of the Newborn

This condition has a high morbidity, and the rate of mortality remains at up to one-fifth despite the advent of treatment with inhaled nitric oxide. The pulmonary arteries fail to remodel after birth, and the vessels remain thick walled. The condition can be idiopathic but is more usually associated with hypoxia. It is a feature of certain types of congenital cardiac disease. Hence, it is multi-factorial in origin, but the nature of the underlying defect causing failure to adapt is uncertain. It has been shown to involve failure of endothelial-dependent and -independent relaxation, a primary structural abnormality of the targeted smooth muscle cells, and an excess of endothelin, possibly also with an excess of other vasoconstrictor agonists such as thromboxane or an isoprostane. Hypoxia, a common cause of the condition, alters the endothelial metabolism of vasoactive agents, such as endothelial nitric oxide synthase, 5-hydroxytryptamine, and angiotensin-converting enzymes.^{69–71} It also increases endothelial permeability, which facilitates leakage of growth factors and blood cells into the underlying layer of smooth muscle cells.²⁹

Role of Specific Mediators

Nitric Oxide

Neonatal pulmonary hypertension affects both release of, and response to, nitric oxide in the pulmonary arteries.^{41,50,72} Chronic hypoxia impairs endothelial calcium metabolism and normal coupling between the enzyme and caveolin-1, thus inactivating the enzyme.⁶⁹ Inappropriate postnatal persistence of an endogenous inhibitor of nitric oxide, such as ADMA, may also cause persistent pulmonary hypertension of the newborn, since it is known to persist at abnormally high levels after birth in such babies.⁵⁴ Arginine deficiency, absolute or relative, is a feature of the human infant with such persistent pulmonary hypertension, and an L-arginine infusion can be associated with an improvement in oxygenation.

Endothelin

The circulating levels of endothelin remain high in experimental models of hypoxia-induced persistent pulmonary hypertension. The density of binding of receptors, primarily the A type, is increased.⁷³ Co-constriction of pulmonary arteries and bronchuses is a well-recognised clinical feature of infants with pulmonary hypertension. Messenger RNA for preproendothelin was significantly elevated in fetal ovine lung tissue after ductal ligation during fetal life, and expression of the A type receptors was elevated.⁷⁴

Prostacyclin

The release of this agent is reduced in many forms of pulmonary arterial hypertension in humans, and is assumed to be low in newborns with persistent pulmonary hypertension. Its administration alleviates hypoxic pulmonary vasoconstriction in both afflicted newborn infants and experimental animals. Systemic hypotension can occur when this medication is used in sick infants.

Activation of Rho GTPases

Rho GTPases are key regulators of endothelial actin dynamics, thereby influencing both vascular reactivity and endothelial permeability.²¹ Activation of RhoA has been associated with the development of pulmonary hypertension,^{8,75} possibly by mediating the effects of vasoconstrictors such as angiotensin II, endothelin-1, and acetylcholine, and downregulating the expression of endothelial nitric oxide synthase in endothelial cells, and hence the production of nitric oxide.²¹

Serotonin Fluoxetine

This selective inhibitor of the uptake of serotonin induced pulmonary hypertension in rats exposed to the drug during fetal life. Pulmonary arterial muscularity was increased.⁷⁶

Endothelial Permeability in Pulmonary Hypertension

Endothelial leakage occurs in pulmonary hypertension, irrespective of aetiology. Inhalation of nitric oxide may prevent pulmonary oedema, by both improving the barrier function of the endothelium and enhancing vascular relaxation.⁷⁷ Overexpression of angiotensin-1 produces leakage-resistant vessels, and angiotensin-1 is protective when used experimentally.⁷⁸ Potential therapeutic approaches include inhibition of VEGF, RhoA, and other molecules.⁷⁹ The natural mediator sphingosine 1-phosphate activates Rac1, and has considerable therapeutic potential.⁸⁰

Treatment

The aim is to control excessive reactivity and structural remodelling by using therapeutic agents which exploit the interactions between the signalling pathways controlling

these events. Clinically, we rely on nitric oxide, inhibitors of phosphodiesterase 5, and less commonly, antagonists of the receptors to endothelin-1. Studies with guanylate cyclase activators are promising. Looking ahead, we know that in animal models the overexpression of vasodilator genes such as endothelial nitric oxide synthase, preprocalcitonin gene-related peptide, and prostacyclin synthase, have produced promising results,⁸¹ as has fasudil, the inhibitor of Rho kinase.⁷⁵ Statins might also be helpful, since they inhibit the prenylation and membrane translocation of Rho proteins, have anti-leakage and anti-inflammatory effects, and increase the availability of endothelial nitric oxide. Perhaps the most logical therapy would be an agent to open the potassium channels.

In summary, we are at last beginning to understand some of the mechanisms regulating pulmonary vascular development and function. Integrating clinical observations with experimental studies, taking advantage of gene targeting, and designing appropriate models of lung development present exciting challenges for the future.

PULMONARY CIRCULATION IN THE SETTING OF CONGENITALLY MALFORMED HEARTS

In children with congenitally malformed hearts, the pulmonary circulation may fail to develop normally, even before birth.

Abnormal Prenatal Development

Abnormalities of pulmonary vascular development arising during fetal life may be divided into primary developmental abnormalities that arise early in gestation and those that are probably secondary to haemodynamic changes caused by the presence of congenital heart disease and develop late in fetal life. Primary abnormalities include an absent right or left pulmonary artery, failure of some or all of the intrapulmonary arteries to connect exclusively with the central intrapericardial pulmonary arteries, a reduction in the number of generations of intrapulmonary arteries, and stenoses of the pulmonary arteries. These abnormalities may occur in children with a normal heart, when they are usually associated with disordered development of the airways. A persistent systemic arterial supply is a feature of a sequestered segment of malformed hypoplastic lung. A reduction in the pulmonary arterial branching pattern is seen in the hypoplastic lung of renal agenesis and dysplasia, congenital diaphragmatic hernia, and rhesus isoimmunisation.^{82–84} Pulmonary arterial stenoses occur in the rubella syndrome, with or without an associated intracardiac abnormality.

Absence of One Pulmonary Artery

Absence of one of the branches of the pulmonary trunk can occur in the presence of a patent pulmonary trunk when the pulmonary artery at the hilum is connected to a vessel arising from the ascending aorta or the aortic arch. This is sometimes known as a distal ductal origin of a pulmonary artery. Occasionally, the hilar pulmonary artery is connected to the right ventricle or aorta by an atretic thread in the position of a pulmonary trunk or arterial duct. In some cases, it is impossible at thoracotomy or postmortem to identify any such structure that might once have

perfused the lung. In some children, serial angiographic studies show that the abnormality was acquired postnatally, usually in association with closure of the ducts. The intrapericardial pulmonary artery is then more correctly described as being interrupted rather than absent. Patients with tetralogy of Fallot are particularly vulnerable to such an acquired change. When no large systemic artery anastomoses with the hilar pulmonary artery, the pulmonary arterial supply is derived from an expanded bronchial circulation. When the intrapericardial pulmonary artery is absent or interrupted, however, the pulmonary artery is usually patent at the hilum, although it is frequently small. Consequently, all such patients should be regarded as potential candidates for correction by insertion of a prosthesis between the pulmonary trunk or right ventricle and the hilar pulmonary artery.

Failure of All Intrapulmonary Arteries to Connect Exclusively with the Intrapericardial Pulmonary Arteries

In the majority of patients with tetralogy of Fallot and pulmonary atresia, the lungs are perfused by large arteries arising from the aorta, called major systemic-to-pulmonary collateral arteries (Fig. 7-5).⁸⁵ Development of the airways is normal. The intrapericardial pulmonary arteries are usually present, although they may be extremely small, or even incompletely canalised. Systemic-to-pulmonary collateral arteries are usually easily distinguishable from the enlarged bronchial arteries seen after birth in several types of congenital disease characterised by a low flow of blood to the lungs. The distinction is, however, sometimes blurred. Occasionally, arteries as large as major collateral arteries appear to have a similar origin from the aorta as do bronchial arteries, and then connect with intrapulmonary

Figure 7-5 The pulmonary arterial branching pattern seen in pulmonary atresia with ventricular septal defect and major aortopulmonary collateral arteries. The solid lines indicate the central pulmonary arteries and their branches, and the cross-hatched, stippled, interrupted, and dotted lines indicate the collateral arteries and the intrapulmonary arteries with which they connect. Ao, aorta. (From Haworth SG, Macartney FJ: Growth and development of the pulmonary circulation in pulmonary atresia with ventricular septal defect and major aortopulmonary collateral arteries. *Br Heart J* 1980;44:14–24.)

arteries to supply the lung. If, as seems probable, pulmonary and bronchial arteries have a common origin from the embryonic pulmonary plexus, this is not surprising. In the presence of collateral arteries, the source of arterial supply to the lungs is frequently complex, and varies in different patients. The complexity of their connections with the intrapulmonary arteries, and with each other, therefore, is also not surprising. In children with tetralogy and pulmonary atresia, a collateral artery may connect with a pulmonary artery at the hilum, and so perfuse both lungs if the intrapericardial pulmonary arteries are patent (see Fig. 7-5). Alternatively, a collateral artery may anastomose end-to-end with a lobar or segmental pulmonary artery and have no connection with the intrapericardial pulmonary arteries at either the hilum or within the lung. More than one collateral artery may perfuse the same intrapulmonary artery at the hilum, which is then said to have a duplicate, or dual, blood supply. Collateral arteries that do not connect with an intrapericardial or hilar pulmonary artery run to the hilum of the lung and then accompany a lobar bronchus until they anastomose with an intrapulmonary artery. As a result, a vessel that has the basic structure of a muscular systemic artery becomes a vessel with the structure of an elastic pulmonary artery.⁸⁶ The pulmonary artery then branches with the airways in a normal manner to perfuse the capillary bed, as in the normal lung. Different bronchopulmonary segments within a lobe may be connected to several different vessels, some segments being connected to an intrapericardial pulmonary artery, and others connecting directly with collateral arteries. Several arteries may, therefore, accompany the main and lobar bronchuses. On angiography, the orderly appearance of one pulmonary artery accompanying each bronchus is lost. The only method of ensuring that the anatomy is understood in each patient is to account for the arterial supply of each bronchopulmonary segment, look for sources of a duplicate supply to each segment, and search for connections between different collateral arteries.

The collateral arteries commonly arise from the descending thoracic aorta behind the origin of the left main bronchus in the presence of a left aortic arch, and almost in the mid-line when the arch is on the right. They may also arise from beneath the aortic arch and, less commonly, from below the diaphragm above the coeliac axis. They frequently divide near their aortic origin. Collateral arteries are commonly stenosed where they anastomose with a hilar or intrapulmonary artery. In postnatal life, a degree of stenosis is desirable to reduce the systemic arterial pressure to a level more suited to the pulmonary circulation. Collateral arteries, however, may be severely stenosed either at their origin from the aorta or, more commonly, in the mid-portion of the vessel between aorta and lung, where the lumen may even be occluded by large mounds of proliferating intimal tissue (Figs. 7-6 and 7-7). It is not uncommon for children to become increasingly cyanosed during the first months of life, probably as a result of progressive intimal proliferation in the collateral arteries. Occasionally, children are born with minute intrapericardial and intrapulmonary arteries, and small or occluded collateral arteries. Multiple systemic-to-pulmonary collateral arteries seen in infants are best regarded as precarious fetal connections. Within the lung, the development of the pre- and intra-acinar arteries before and after birth depends on the lumen diameter of the perfusing vessels.

Figure 7-6 Transverse section of the mid-portion of a collateral artery at a region of segmental narrowing. The lumen of this muscular artery is almost totally obliterated by intimal proliferation (IP) and cushion formation and a layer of amorphous material containing no elastic tissue. EL, external elastic lamina; IL, internal elastic lamina; M, media; PA, pulmonary artery. (Miller's elastic stain.)

Figure 7-7 Post-operative injection into aortopulmonary anastomosis shows central pulmonary arteries, stenoses (arrows) and aneurysmal dilation at origin of left upper and lower lobe arteries; it also shows that central vessels perfuse only a minority of bronchopulmonary segments.

Most infants with tetralogy and pulmonary atresia suffer from the effects of hypoperfusion. Occasionally, the collateral arteries have a more elastic mural structure, being large vessels that provide a good, or even excessive, blood supply to the lung. Such patients present later. Large collateral arteries expose the distal intrapulmonary arteries to a high pressure, which can lead to the development of pulmonary vascular obstructive disease. When the lungs are perfused by an arterial duct, all the intrapulmonary arteries are usually connected to the hilum. A duct may, however, connect with a hilar pulmonary artery to perfuse some bronchopulmonary segments, while major systemic-to-pulmonary collateral arteries provide the only blood supply to other segments. Supply through bilaterally persistent arterial ducts can also be found.

Approximately two-thirds of patients present in infancy; at presentation, half are severely cyanosed and one-quarter are in heart failure.⁸⁷ In hypoperfused patients, the aim of surgery is to increase the supply to encourage growth of both intrapericardial and peripheral pulmonary arteries. All, or at least most, bronchopulmonary segments in each lung should connect, or be made to connect by unifocalisation, to an intrapericardial pulmonary artery or conduit, either as a prelude to, or at the time of, definitive repair. Collaterals should not be ligated unless an alternative source of arterial supply can be demonstrated. Since the anatomy is exceedingly variable, management must be individually tailored to each patient. The anatomy should be defined at presentation and the long-term management planned accordingly. Staged surgical procedures may be required to make a patient a candidate for complete repair. The morphological substrate is the limiting factor, and some patients will do better for longer without surgical intervention and eventually be candidates for transplantation.

Developmental Abnormalities of the Intrapulmonary Arteries

The various types of congenital cardiac disease may be regarded as vicarious experiments in which to study the relationship between changes in pulmonary arterial pressure and flow and structural development. Aortic valvar atresia, or critical stenosis, and pulmonary atresia with an intact ventricular septum, cause different and almost diametrically opposite structural abnormalities of the intra-acinar pulmonary arteries. In critical aortic stenosis or atresia, the entire cardiac output is ejected into the pulmonary trunk, and the body is perfused by the arterial duct. During fetal life, there is an increase in pulmonary arterial muscularity, and the number of intra-acinar arteries per unit area of lung may be increased.⁸⁸ At birth, the babies have severe pulmonary hypertension. It is now well established that those undergoing the Norwood sequence of operations can subsequently be converted to the Fontan circulation, indicating a marked reduction in pulmonary vascular resistance. By contrast, children with pulmonary atresia in whom the arterial duct is the only source of blood supply to the lung are born with abnormally small thin-walled pre- and intra-acinar arteries, and may have a reduction in the number of intra-acinar arteries.⁸⁹ Before birth, the pressure generated by the left ventricle is probably not transmitted to the pulmonary circulation across the rather small, abnormally angulated duct found in these patients. When the duct is

relatively large, however, pulmonary arterial muscularity develops normally and intra-acinar arterial multiplication is almost normal.

Babies with totally anomalous pulmonary venous connection who present with obstructed venous return during the first week of life may show a marked increase in muscularity of both intra-pulmonary arteries and veins.^{90,91} The findings are consistent with prenatal obstruction to pulmonary venous return. In those with the infradiaphragmatic type of anomaly, the descending vein can be narrowed or even occluded by fibrous tissue at birth. Also, the extrapulmonary veins may be smaller than normal and show intimal proliferation. Within the lungs, the increased muscularity is potentially reversible. In the extrapulmonary veins, however, prenatal obstruction may instigate intimal proliferation and fibrosis that can progress despite a technically successful operation. Post-operative stenosis then develops at some distance from the suture lines. Patients with the infradiaphragmatic type of anomaly are particularly vulnerable.

These findings in the pulmonary circulation of patients with aortic atresia or stenosis, pulmonary atresia, and totally anomalous pulmonary venous connection demonstrate the vulnerability of the fetal pulmonary circulation to changes in pressure and flow, and show how the structural changes in the lung can prejudice survival.

Effects of Pulmonary Hypoperfusion

The effects of hypoperfusion on the developing pulmonary circulation may be as deleterious as those of hyperperfusion. The intrapericardial pulmonary arteries may be minute. The proximal elastic arteries may contain less elastin than normal, while the intra-acinar arteries are usually smaller, and have a thinner muscle coat, than normal. Pulmonary arterial thrombosis can occur, leading to eccentric areas of intimal fibrosis, characterised by a peculiar form of recanalisation in which strands of fibrous tissue of varying thickness divide the arterial lumen into several channels. The aetiology and incidence of thrombotic lesions is uncertain, but they are thought to relate to the degree of polycythaemia. Enlargement of the bronchial arterial circulation to supplement, or even to replace, a normal pulmonary arterial blood supply occurs in many forms of cyanotic congenital heart disease, such as tetralogy of Fallot and pulmonary atresia. An enlarged bronchial arterial circulation is rarely found in newborn infants with an abnormally low pulmonary blood flow. Infants with pulmonary atresia and intact ventricular septum die when the duct closes because the bronchial arterial circulation is not sufficiently enlarged at that time. In older patients with tetralogy and pulmonary atresia, an enlarged bronchial arterial circulation is frequently seen at angiography. Serial cardiac catheterisation studies in such patients frequently show progressive enlargement of the bronchial arterial circulation. When the lung is severely hypoperfused, the development of the alveoluses can be impaired. Postmortem lung volume is reduced in children dying of tetralogy of Fallot. Performing a corrective operation before the end of the critical period of growth of the lung presumably encourages normal alveolar development. In addition, an early repair permits greater physical activity. In normal children, physical training increases total lung volume and vital capacity. Fortunately, the full impact of pulmonary hypoperfusion

on the developing lung is rarely seen nowadays, since the flow can be increased as early as is necessary by medical or surgical treatment, be it palliative or corrective.

Growth of small pulmonary arteries is encouraged by surgically increasing the flow of blood through them for some time before performing the definitive repair. Whether the arteries will grow sufficiently to permit definitive repair depends upon their initial size, surgical expertise in increasing flow through them, and the extent of peripheral runoff. The potential for growth of both intrapericardial and peripheral pulmonary arteries is uncertain. Increased distensibility of a vessel consequent upon an increase in flow must be distinguished from growth. While in the reported studies the magnitude of the response and the relatively long time interval between operation and restudy suggests that growth has indeed occurred, we do not know whether or not these vessels will grow sufficiently to achieve a size appropriate to the size of the lung and that of the child. That the growth potential may not be normal is suggested by the abnormal structure of the wall of extrapulmonary vessels when pulmonary blood flow is low, abnormalities which change the mechanical properties of the wall and, hence, their physical response to an increase in flow.

PULMONARY HYPERTENSION

Pulmonary hypertension is a condition which causes immense suffering. A modest elevation in pulmonary arterial pressure is tolerable, but a high pressure is associated with obstructive pulmonary vascular disease leading to right-sided failure and death. The scene has changed so dramatically since the millennium. Improved diagnostic techniques facilitate assessment, and we now have a clinically useful classification (Table 7-1). Pulmonary arterial hypertension is subdivided into the idiopathic and familial form and the pulmonary hypertension associated with other disorders, such as congenital cardiac disease. For those with established pulmonary vascular disease, discoveries of therapeutic agents have revolutionised management. They do not, however, cure the basic problem of pulmonary vascular disease.

Pulmonary hypertension itself is defined as a mean pressure within the pulmonary arteries equal to or greater than 25 mm Hg at rest, or 30 mm Hg on exercise, a definition which applies to all but the youngest infants.

The commonest causes of pulmonary hypertension in children are congenital heart disease and persistent pulmonary hypertension of the newborn. Children can also suffer from idiopathic pulmonary arterial hypertension, previously known as primary pulmonary hypertension. The patient is said to be suffering from the idiopathic form when there is no identifiable explanation for the increase in pulmonary arterial pressure. Idiopathic pulmonary arterial hypertension has been the subject of intense research because it is the most pure form of pulmonary hypertension, and new medicines have been evaluated and studied in this condition.

Pulmonary Hypertension in Those with Congenitally Malformed Hearts

Diagnosis of unrepaired congenital cardiac malformations calls for experienced assessment of likely operative outcomes, particularly the risk of acute post-operative and of

long-term sustained pulmonary hypertension with continued evolution of pulmonary vascular disease.

Pre-operative Assessment of the Hypertensive Pulmonary Circulation

The cardiologist is constantly trying to predict the structural changes present in the lungs from the clinical, radiological, and haemodynamic findings without having to resort to a biopsy of the lung. Prediction can be difficult.

The clinical history is important. Cardiac failure may appear to improve as pulmonary vascular resistance increases. High flow of blood to the lungs is frequently associated with recurrent infections of the respiratory tract. Dilated pulmonary arteries compress the main and lobar bronchuses in children with and without pulmonary hypertension, leading to the familiar problem of recurrent collapse of different lobes or segments of lung. Not infrequently, the respiratory complications of congenital cardiac disease constitute an indication for corrective surgery in infancy. After operation, the bronchial deformity may persist for some time. Indeed, in some patients, prolonged compression appears to be associated with bronchomalacia. Rarely, babies may present to the paediatrician with a history of episodic collapse, indicative of pulmonary hypertensive crises. A labile pulmonary

vasculature in the presence of an intact ventricular septum can be hazardous before as well as after surgical intervention. The extent of the problem is unknown.

The chest radiograph is reassuringly plethoric when the resistance is sufficiently low to permit a high flow to the lungs, and it is depressingly evident when pulmonary vascular disease is advanced. The development of severe obstructive disease in the muscular pulmonary arteries leads to peripheral pruning and a hypertranslucent appearance in association with dilation of the hilar and proximal vessels. Wedge angiography is not widely used, but it is helpful in demonstrating advanced pulmonary vascular obstructive disease, and should always be used in concert with other examinations in assessing whether the patient may still be able to undergo corrective surgery. If performed by balloon occlusion, the abnormal pulmonary wedge angiogram is characterised by decreased arborisation, reduced background opacification, and delayed venous filling. The arteries may appear tortuous, have segments of dilation or constriction, and have marginal defects suggestive of obliterative disease. Quantitative wedge angiography represents an attempt to improve the correlation between structure and function.⁹² In the normal lung, the pulmonary arteries taper towards the periphery, but the vessels narrow over a shorter distance in the presence of an elevated pulmonary vascular resistance.

Pulmonary arterial pressure can be estimated non-invasively by Doppler ultrasound, but resistance cannot. At cardiac catheterisation, the lowest determinations of pulmonary arterial pressure and vascular resistance are conventionally accepted as a guide to outcome. This is based on the premise that, if the predominant structural abnormality in the pulmonary circulation is an increase in muscularity, it will respond to vasodilator substances. To this end, the patient is usually given nitric oxide. With any vasodilator, the release of vasoconstrictor tone will lower pulmonary vascular resistance and increase the magnitude of the left-to-right shunt, and may lower the pulmonary arterial pressure. Failure to achieve this response implies fixed and organic obstruction of the pulmonary circulation. Children with Down syndrome are particularly difficult to assess because they often suffer from obstruction of the upper airways, which may contribute to the increased pulmonary vascular resistance determined at cardiac catheterisation. The pathologist will then find less pulmonary vascular

damage in a lung biopsy than expected for the increase in pulmonary arterial pressure and resistance. The use of oxygen to calculate vasoreactivity is usually more problematic than the use of nitric oxide. In both cases, consumption of oxygen should be measured, and dissolved oxygen should be taken into account when oxygen is added to nitric oxide to test reactivity.

The structural abnormalities present in the lung can usually be predicted from the type of intracardiac abnormality, the age of the child, and the haemodynamic findings at cardiac catheterisation. In more complex cardiac abnormalities, and if there is ever doubt about the likely outcome of intracardiac repair, an open lung biopsy should help clarify the position. It is also helpful in predicting prognosis even if the decision is taken to go ahead with the corrective operation.

Development of Pulmonary Vascular Disease

Children are occasionally born with pulmonary vascular disease, but this is rare. Pulmonary vascular disease usually starts at birth with abnormal postnatal remodelling, abnormal muscularisation of distal pulmonary arteries, and a reduction in the number of vessels. This is followed by obstructive intimal proliferation, and ultimately to formation of plexiform lesions if the pulmonary arterial pressure is allowed to remain high (Fig. 7-8). Current thinking is that endothelial injury leads to programmed cell death and loss of small vessels. Endothelial injury is manifest as impaired endothelial dependent relaxation, defective levels of von Willebrand factor⁹³ and fibrinolysis. The progressive thickening of the wall of the more proximal intra-acinar and pre-acinar muscular arteries, and the obliteration associated with neointimal formation, has been related to heightened proliferation and migration of cells that have markers of smooth muscle cells because they are positive for α -smooth muscle actin. These cells may represent a specialised subpopulation, have originated as stem cells or fibrocytes, may be transformed fibroblasts or endothelial cells, or all of the above. With progressive obstruction, plexiform lesions develop. Endothelial proliferation is characteristic of this lesion, leading to the formation of aberrant channels in the obliterated lumen and in the adventitia. These lesions are thought to reflect clonal expansion of an endothelial cell resistant to death,⁹⁴ or of

Figure 7-8 The end of four arterial pathways from the pre-acinar (PRE) and terminal bronchiolar arteries (TB) to the intra-acinar respiratory bronchiolar (RB) and alveolar duct (AD) arteries, showing the gradual development of intimal proliferation (stippling) associated with a progressive increase in wall thickness of pre-acinar arteries and decrease in alveolar wall (AW) thickness of intra-acinar arteries until dilation lesions develop. The upper interrupted line indicates the plane of section of satisfactory biopsies, and the lower line the plane of section of biopsies taken too close to the pleura to sample the distal pre-acinar and all the intra-acinar vessels.

circulating endothelial progenitor cells. Pulmonary arterial endothelial cells from patients with idiopathic pulmonary hypertension are known to produce decreased amounts of nitric oxide on the basis of high levels of arginase, show exaggerated proliferation in response to growth factors, and exhibit high rates of glycolysis.⁹⁵ Additional pathological features include thickening of the pulmonary adventitial layers and venous hypertrophy. Immunohistochemical studies have revealed increased expression of transforming growth factor beta (TGF- β), matrix proteins such as collagen, elastin, fibronectin, tenascin-C, and glycosaminoglycans, macrophages, and T cells, as well as agents associated with inflammation, such as S100A4/Mts1 and fractalkine.⁹⁶

The intimal obstruction to flow is strategically placed at the entrance to each respiratory unit (see Fig. 7-8). As in transposition with ventricular septal defect, such obstruction can increase resistance to flow during the first months of life.⁹⁷ In babies, these changes occur before the development of marked intimal fibrosis, and other features characteristic of advanced pulmonary vascular disease in older patients, have had time to develop. Intimal proliferation in infants is cellular rather than fibrous. The cells are loosely organized rather than being arranged in a neat circumferential fashion, and the onionskin picture of laminar intimal fibrosis is uncommon. Even in older children, fibrinoid necrosis and arteritis are rare findings. As intimal proliferation increases in severity in the small muscular arteries, it narrows the lumen, and the medial thickness of the more peripheral respiratory unit arteries decreases (Fig. 7-9). The transitory near-normal appearance of the peripheral intra-acinar arteries can be misleading, because it reflects the severity of more proximal obstruction in patients with a high pressure and resistance. In order to interpret a lung biopsy with confidence, therefore, it is important that the biopsy be sufficiently deep to include some of the pre-acinar and terminal bronchiolar arteries in which intimal proliferation first develops.⁹⁸ The appearance of these arteries is crucial to the evaluation of the intra-acinar arteries beyond. If pre-acinar arteries are not present in the specimen, however, a mean medial thickness of less than one-sixth in arteries from 50 to 100 μ m in diameter, particularly when associated with respiratory unit arteries slightly larger than normal for age, is suspicious of pre-dilation in patients with severe pulmonary hypertension and elevated

resistance. This stage in the evolution of pulmonary vascular disease is associated with an increase in mortality and morbidity at and after intracardiac repair. The number of intra-acinar arteries is reduced in the presence of severe pulmonary hypertension. Ultrastructural examination reveals many occluded vessels.⁹⁹ This is an early change and can be seen in young infants in the presence of a low resistance. Whether there is also a primary failure of postnatal angiogenesis is unknown. When the pulmonary arterial pressure remains elevated after birth, whatever the reason, the structure of the pulmonary trunk retains its fetal appearance, and contains long, thick elastin fibres. If pulmonary hypertension develops later in life, the pulmonary trunk becomes thicker through the deposition of connective tissue, and smooth muscle cells are hypertrophic in a normally adapted vessel.

Classification of Pulmonary Vascular Disease

In 1958, Heath and Edwards published their classical papers on the evolution of pulmonary vascular disease.^{100–102} They classified pulmonary vascular disease into six grades, in order of increasing severity (Table 7-2). The structural features of each grade were related to measurements of pulmonary arterial pressure, flow, resistance and patient outcome. In Figures 7-10 and 7-11, we illustrate the first three grades, and in Figure 7-12, we show the features of the transitional fourth grade. Although the first three grades reflect a succession of structural changes, the subsequent grades probably do not. Necrotizing arteritis can precede the development of plexiform lesions. None of the advanced lesions carries a more severe prognosis than the others, save for the plexiform lesion. All the patients with congenital cardiac disease studied initially by Heath and Edwards were at least 10 months of age. Younger patients were excluded from the analysis because the lungs showed less structural change

TABLE 7-2

GRADING CLASSIFICATION FOR PULMONARY VASCULAR DISEASE

Grade	Structural Features	Characteristics
I	Medial hypertrophy	High resistance, high reserve pulmonary vascular bed still labile
II	Medial hypertrophy with cellular intimal proliferation	
III	Progressive fibrous occlusion	
IV	Progressive generalized arterial dilation with the formation of complex dilation lesions	Transitional stage
V	Chronic dilation with numerous dilated vessels throughout the lung plus pulmonary haemosiderosis	High resistance, low reserve pulmonary vascular bed no longer labile because of luminal occlusion
VI	Fibrinoid necrosis of the media Arterial dilation with the formation of complex dilation lesions	

Figure 7-9 Photomicrograph of the lung of a 5-month-old infant with transposition and ventricular septal defect showing a terminal bronchiolar artery, distended by injection medium, having a thick media (M). Intimal proliferation (IP) surrounds the origin of the thin-walled branches. IEL, internal elastic lamina. ($\times 130$.)

Figure 7-10 Photomicrograph of lung tissue from a 3-month-old child with a ventricular septal defect, showing severe medial hypertrophy. ($\times 496$.)

Figure 7-12 Photomicrograph of lung tissue from an 11-month-old child with a common arterial trunk. Injection medium distends an artery, showing medial hypertrophy (M) with circumferential intimal proliferation (IP). ($\times 267$.)

than was expected for the elevation in pulmonary vascular resistance. A more recent classification¹⁰³ concentrates on the early structural changes when medial hypertrophy is developing, before fibrotic intimal damage appears. All classifications have their limitations and the biopsy findings in any individual must be interpreted in the light of the clinical picture in that patient. Medial hypertrophy is usually associated with a low pulmonary vascular resistance and is potentially reversible. In young children, resistance may be high, and the children may die after a technically successful intracardiac repair because the pulmonary arterial pressure is high, either continuously or sporadically; the episode is then described as a pulmonary hypertensive crisis. Medial hypertrophy, although a potentially reversible lesion, is not necessarily a safe lesion. At the other extreme, extensive dilation plus the other features of classical pulmonary vascular disease of the sixth grade are invariably associated with a high resistance and a poor prognosis. In practice, however, most patients fall between the two extremes. The use of a semiquantitative descriptive analysis of arterial mural structure, combined with quantitative morphometry

of arterial muscularity and size, has helped identify a high-risk pre-dilation phase of pulmonary vascular disease, seen most often in children younger than 2 years.⁹⁸

Evolution of Pulmonary Vascular Disease in Common Types of Congenital Cardiac Disease

In children with severe pulmonary hypertension, the rate of development of pulmonary vascular change depends upon the type of intracardiac abnormality (Fig. 7-13). For example, both a large isolated ventricular septal defect and one associated with discordant ventriculo-arterial connections cause pulmonary hypertension, but while the former rarely causes severe pulmonary vascular disease during the first year, the latter causes irreparable damage.

Ventricular Septal Defect

In children with a hypertensive ventricular septal defect, the peripheral pulmonary vasculature fails to develop normally after birth⁹⁸ (Fig. 7-14). Pulmonary arterial muscularity increases in both pre- and intra-acinar arteries from early

Figure 7-11 Photomicrographs of the lung biopsy of a child aged 19 months who had a ventricular septal defect and a mean pulmonary arterial pressure of 51 mm Hg, and died at operation. A, Cellular intimal proliferation (IP) in an artery accompanying a respiratory bronchiolus. B, A more peripheral vessel accompanying an alveolar duct. Note absence of medial hypertrophy. M, media; MH, medial hypertrophy.

Figure 7-13 The mean percentage arterial medial thickness is given by $2(\text{medial thickness}) (\text{external diameter}) \times 100$. The figure shows its value in arteries 50–100 μm in diameter at various ages in 90 children with a ventricular septal defect (VSD), in 38 with an atrioventricular septal defect (AVSD), and in 28 with complete transposition and ventricular septal defect (TGA/VSD).

infancy. Occluded alveolar walls are seen on electron microscopic examination. Intimal proliferation tends to develop towards the end of the first year, and fibrosis during the third year of life. Patients with severe pulmonary hypertension

should therefore undergo surgery before the age of 1 year. A few children develop severe early obstructive intimal proliferation, with the arteries beyond the obstruction having a relatively normal arterial medial thickness. This finding is associated with a pulmonary arteriolar resistance greater than 6 units/ m^2 in the absence of the generalised arterial dilation or other stigmas of pulmonary vascular disease of the fourth grade.

Transposition

In the days before Rashkind septostomy, the average life expectancy was 1.3 months in cyanotic babies with transposition and an intact ventricular septum.¹⁰⁴ Those with a ventricular septal defect survived longer because a higher effective pulmonary blood flow ensures a greater systemic arterial saturation. The presence of a large ventricular septal defect, however, leads to the rapid development of severe pulmonary vascular disease. Persistent patency of the arterial duct also leads to the early development of pulmonary vascular disease. A duct should be closed surgically at 3 months of age if it has not closed spontaneously. In transposition as a whole, outcome correlates with the pulmonary arterial pressure.¹⁰⁵ With transposition and an intact ventricular septum, the pulmonary circulation usually adapts normally to extra-uterine life. The bronchial circulation is enlarged, making a large but unknown contribution to total flow of blood to the lungs. Angiography suggests that the bronchial flow is high from birth. An enlarged bronchial circulation can sometimes persist after successful intracardiac repair. In the presence of a large ventricular septal defect, the pulmonary vasculature does not remodel normally after birth, and this failure to remodel marks the onset of pulmonary vascular obstructive disease¹⁰⁶ (see Figs. 7-9 and 7-13). Intimal proliferation is

Figure 7-14 Postmortem arteriograms from a 9-month-old child with a ventricular septal defect (A) and from a normal child of the same age (B) ($\times 0.50$). (From Haworth SG, Sauer U, Buhlmeyer K, Reid L: Development of the pulmonary circulation in ventricular septal defect: A quantitative structural study. *Am J Cardiol* 1977;40:781–788.

seen from 2 months of age, and is abundant by 5 months.⁹⁷ As the intimal obstruction increases in severity, the muscularity decreases in more distal vessels (see Fig. 7-13). After the age of 7 to 9 months, the medial thickness is normal, or even less than normal, in the distal vessels. These patients, without medial hypertrophy despite a high pulmonary resistance, are usually inoperable.

Atrioventricular Septal Defect

Cellular intimal proliferation develops earlier and is more severe in babies with an atrioventricular septal defect than in those with an isolated ventricular septal defect (see Fig. 7-13). Severe medial hypertrophy and intimal proliferation can be present by 6 or 7 months of age, and intracardiac repair should be carried out in early infancy.¹⁰⁷ Children of all ages can have a high pulmonary vascular resistance of 6 units/m² or more. In those under 3 months of age, however, the pulmonary arteries usually have increased muscularity, with or without intimal proliferation.

Atrial Septal Defect in the Oval Fossa

Pulmonary hypertension rarely develops in children with defects of the floor of the oval fossa. Those who develop pulmonary hypertension often have inoperable disease or do not survive surgery. Their pulmonary vasculature shows severe obstruction with intimal fibrosis. Such patients probably have idiopathic pulmonary hypertension with an associated atrial communication. The pulmonary vascular abnormalities in these children with pulmonary hypertension are unlike those seen in most middle-aged patients with defects in the oval fossa and cardiac failure, and more like those of children with a hypertensive ventricular septal defect. The pre-acinar arteries in older patients usually undergo a modest increase in pulmonary arterial muscularity and are dilated, while the dominant change at the periphery is fibrotic occlusion of small alveolar duct and the alveolar wall arteries, leading to a reduction in the capacity of the peripheral pulmonary vascular bed.

Abnormalities Causing Pulmonary Venous Obstruction

Totally anomalous pulmonary venous connection is primarily a disease of early infancy, presenting at or soon after birth. When the venous return is supradiaphragmatic, flow to the lungs is elevated for some time before obstruction develops. The intrapulmonary arteries and veins show increased mural thickness, the amount depending on the duration and severity of the obstruction. In infants with the infradiaphragmatic type of return, obstruction and vascular abnormalities are frequently present at or soon after birth, indicating intra-uterine change.⁹¹ Pulmonary hypertension subsides after repair in almost all patients, and the pulmonary vascular changes apparently regress. Children with infradiaphragmatic return may occasionally have intrinsically small extrapulmonary veins, and pulmonary hypertension may then persist despite adequate reconstruction.⁹¹

In other cardiac abnormalities causing pulmonary venous obstruction, such as divided left atrium, congenital mitral stenosis, and stenosis of individual pulmonary veins at their junction with the left atrium, the vascular abnormalities are similar to those in totally anomalous pulmonary venous connection, but the arterial changes are less prominent. The lymphatic channels are dilated and abnormally thick walled, and the perivascular connective tissue is abnormally dense.

Scimitar Syndrome

Pulmonary hypertension is not usually a feature of the scimitar syndrome when the diagnosis is an incidental finding in older patients, but it can occur in babies. In four children with the syndrome presenting at between 1.5 and 4 months of age, microscopic examination showed normal development of the peripheral airways and alveolar regions.¹⁰⁸ The pulmonary arterial branching pattern was deficient in three, and in areas of lungs not perfused by the right pulmonary artery, the systemic arteries from the upper abdominal aorta anastomosed with the pulmonary arteries to distribute blood to a dilated capillary bed. Pulmonary arterial medial wall thickness was increased, but venous morphology was normal. Early correction is recommended.

Operability and Survival after Cardiac Repair

The outcome of a satisfactory intracardiac repair in patients with pulmonary hypertension is determined by the state of the pulmonary vascular bed at the time of repair. Operability and the reversibility of pathological lesions are not synonymous. Pulmonary arterial medial hypertrophy with or without a modest amount of cellular intimal proliferation may be potentially reversible, but it is not always a safe lesion. It is associated with pulmonary hypertensive crises. Hypoxia is probably the most common precipitating factor, but other, unrecognised and unknown, factors no doubt operate. Crises tend to cluster and can be fatal. Complete obliteration of the arterial lumen by intimal proliferation, even when highly cellular, is not usually reversible. Plexiform lesions are regarded as irreversible. It is not entirely certain whether these lesions are irreversible when present in early childhood. Given the severity of obstructive pathology with which they are associated, however, reversibility seems unlikely. The reduction in small intra-acinar arteries seen particularly in young children with severe pulmonary hypertension is probably not reversible.⁹⁹ The age at which intracardiac repair is carried out is the most crucial factor, and it is now well recognised that abnormalities are best repaired in early infancy. The emphasis in clinical management, therefore, must be on prevention of pulmonary vascular disease. When the natural history of the cardiac abnormality is that of rapidly progressive pulmonary vascular disease, as in transposition with ventricular septal defect, or hearts with univentricular atrioventricular connection in the absence of obstruction to the pulmonary outflow tract, then the child should undergo corrective or palliative surgery soon after birth. Where the natural history of pulmonary vascular disease is less aggressive, as in a ventricular septal defect, the abnormality should be corrected before 1 year of age if the pulmonary arterial pressure remains high in the presence of a large defect.

Medical Treatment of Pulmonary Hypertension

The beneficial effect of the drugs used to treat idiopathic pulmonary hypertension has encouraged extension of their use to pulmonary arterial hypertension of other aetiologies. Most children with post-operative pulmonary hypertension have a modest increase in pulmonary arterial pressure, but those symptomatic children in whom the pulmonary arterial pressure is equal to, or approaching,

systemic level are treated as though they have the idiopathic form. In patients with the Eisenmenger syndrome, the clinical picture varies considerably. Many untreated patients have a good quality of life for many decades, but some are severely limited. The new specific therapies available for oral use can help. Bosentan can improve both exercise tolerance and haemodynamic parameters in these patients, without a reduction in systemic arterial saturations of oxygen.^{109,110}

Effect of Palliative Surgery on the Lung

In patients with pulmonary hypoperfusion, insertion of a systemic-to-pulmonary shunt may lead to pulmonary hypertension. In patients with congenitally malformed hearts associated with pulmonary hypertension, banding the pulmonary trunk may fail adequately to reduce the pulmonary arterial pressure and flow. This may be acceptable if the repair will include a subpulmonary ventricle, but can compromise and prejudice the outcome of conversion to the Fontan circulation or cardiac transplantation.

ACQUIRED HEART DISEASE

Rheumatic Heart Disease

In developing countries, rheumatic heart disease is a common cause of pulmonary hypertension. In India, some children develop mitral stenosis very rapidly after having rheumatic fever and require intervention by 6 years of age, or less. The pulmonary vascular abnormalities in children with rheumatic mitral stenosis are generally more severe than in adults. Pulmonary arterial pressure, nonetheless, usually falls after valvotomy. Balloon mitral valvotomy has revolutionised the management of this condition.

Left Heart Disease

Long-standing disease of the left heart causes pulmonary hypertension and structural changes in the vasculature, which can prejudice cardiac transplantation. Chronic intravenous epoprostenol has reduced pulmonary vascular resistance in some of these patients, making it possible to transplant the heart rather than both heart and lungs.

IDIOPATHIC PULMONARY ARTERIAL HYPERTENSION

Interest in the condition dates back to the early 1950s, when Paul Wood identified six cases during a study of 233 patients with congenitally malformed hearts. As noted by Dresdale, a familial tendency to develop the disease was discovered by Dressler in 1954, and is now known to account for one-twentieth of cases. The therapeutic breakthrough came in 1984, when intravenous prostacyclin was first used therapeutically.^{111,112} The efficacy of this treatment was subsequently proven in adults, and benefit was later demonstrated in children.^{113,114} The first effective oral therapy, bosentan, was introduced in 2002,¹¹⁵ followed by the inhibitor of phosphodiesterase 5, sildenafil.¹¹⁶ The beneficial effect of these drugs has encouraged extension of their use to pulmonary arterial hypertension of other aetiologies. The new therapies treat arterial rather than venous disease. Left untreated,

children with idiopathic pulmonary hypertension fare less well than adults. The predicted survival after diagnosis is less than a year, compared with almost 3 years in adults.^{117,118}

The introduction of specific therapies has improved the prognosis in children as well as adults. Before the definitive trial of intravenous epoprostenol, the only medications available were calcium channel antagonists,¹¹⁹ which we now know are efficacious in the long term in only a minority of patients. Anticoagulation was, and is, also considered helpful.¹²⁰ After the introduction of bosentan in adults, we and others showed that it was also efficacious in children.^{121,122} The inhibitor of phosphodiesterase 5, known as sildenafil, was shown to be efficacious in a short 12-week trial in adults with idiopathic pulmonary hypertension.¹¹⁶ Rates of survival of up to four-fifths at 5 years are now reported.^{123,124} A good quality of life can be assured for many years, but ultimately lung transplantation is necessary in most patients.

Diagnostic Strategy

The patient is said to be suffering from idiopathic pulmonary arterial hypertension when there is no identifiable explanation for the increase in pulmonary arterial pressure. In any patients with pulmonary hypertension, the clinician must exclude any causation which is amenable to treatment, be it medical or surgical.

Clinical Suspicion of Pulmonary Hypertension

Pulmonary hypertension should be suspected in any child who is unduly short of breath, tires easily, or is syncopeal when there is no evidence of cardiac or pulmonary disease. The disorder should also be suspected in those known to suffer from these diseases, and in whom increasing shortness of breath cannot be explained by the underlying disease process itself. The commonest misdiagnosis is asthma. The physical signs of pulmonary hypertension include a left parasternal, right ventricular lift, an accentuated pulmonary component of the second heart sound, and sometimes cool extremities. A diastolic murmur of pulmonary regurgitation may be present, but signs of overt right-sided cardiac failure are a late event in young children.

Confirming the Clinical Suspicion of Pulmonary Hypertension

An accurate and complete diagnosis is essential, remembering that dual pathology is not uncommon in pulmonary hypertensive children. A chest radiograph, an electrocardiogram, and a transthoracic echocardiogram, including Doppler interrogation, are mandatory. The classical findings include a chest radiograph showing enlarged intrapericardial pulmonary arteries, and diminished peripheral pulmonary vascular markings. The electrocardiographic findings include evidence of right ventricular dilation and hypertrophy, which can be confirmed by transthoracic echocardiography. Doppler interrogation can estimate pulmonary arterial systolic and diastolic pressures. The right ventricular systolic pressure is estimated from the velocity of the regurgitant systolic flow across the tricuspid valve, and the estimated right atrial pressure, using the Bernoulli equation in which the pressure is equal to four times the velocity squared plus the right atrial pressure.

A regurgitant jet across the tricuspid valve is found in the majority of pulmonary hypertensive patients. Echocardiographic measures of right ventricular function include the Tei index, which is the sum of the periods of isovolumetric contraction and relaxation time divided by the period of ejection. It assesses both systolic and diastolic function. The systolic excursion of the tricuspid annular plane correlates with the right ventricular ejection fraction. Blood tests may show elevation of brain natriuretic peptide, although less reliably than in adults. Functional capacity is graded according to the classification of the New York Heart Association, from the asymptomatic patient in the first class to the severely disabled in the fourth class. An objective assessment of exercise capacity is helpful. In a co-operative child of 6 years or more, the results of a 6-minute walk test can be compared with those in normal children of the same age and sex.¹²⁵ Cardiopulmonary exercise testing to determine maximum uptake of oxygen, rate of work, and anaerobic threshold can also be helpful. This test, however, should be carried out after the severity of the pulmonary hypertension has been ascertained at cardiac catheterisation, and it is known that it is safe to stress the child.

Investigations

The systemic arterial oxygen saturation is normal in the absence of interatrial shunting. Desaturation can occur in the presence of right-to-left interatrial shunting. The electrocardiographic findings are characteristic, and include right-axis deviation, evidence of right ventricular hypertrophy with or without a pattern of strain, and right atrial enlargement. In addition to an abnormal chest radiograph, contrast-enhanced spiral computed tomography of the lungs is indicated in older patients to exclude thrombus in the intrapericardial pulmonary arteries, and chronic thromboembolic disease. It is also helpful in distinguishing idiopathic pulmonary arterial hypertension from pulmonary veno-occlusive disease. Ventilation/perfusion scans can be normal in idiopathic pulmonary arterial hypertension, but may show small peripheral non-segmental defects of perfusion. Magnetic resonance imaging can help assess right ventricular function, but is not yet part of the routine work-up in children suspected of having idiopathic pulmonary arterial hypertension. The echocardiogram generally reveals dilated right heart chambers, right ventricular hypertrophy with posterior bowing of the ventricular septum and of the atrial septum when it is intact.¹²⁶

The left ventricle may be severely compressed. In adults, right atrial size and the index of left ventricular eccentricity are predictive of outcome, and should be routinely assessed in children. Testing pulmonary function can sometimes demonstrate obstruction of the small airways. In addition to routine haematology and biochemistry, tests of thyroid function, a screen for thrombophilia, including antiphospholipid antibodies, and an auto-immune screen should all be performed. Children may seroconvert when they are older. Some children have a deficiency of immunoglobulin. They may have a low level of antithrombin III, protein S, or protein C, which may be genetic in origin, or result from a consumption coagulopathy. It is also necessary to screen siblings for the familial form of the disease.

Cardiac Catheterisation to Confirm the Diagnosis, Assess the Severity of Disease, and Guide Therapeutic Management, Including the Role of Lung Biopsy

The purpose of cardiac catheterisation in children with pulmonary hypertension is to confirm the diagnosis, and to ensure that the conclusions drawn from the non-invasive tests were complete and accurate. The catheterisation also determines the severity of the disease by determining accurately the pulmonary arterial pressure, the pulmonary vascular resistance, and the vasoreactivity of the pulmonary vasculature. The main determinant of treatment is the response to testing the potential for vasodilation with nitric oxide during cardiac catheterisation. Adequate sedation, optimal ventilation, and meticulous attention to the acid-base state and loss of blood are mandatory. The clinical history and the haemodynamic findings may indicate the need for further interventions, such as the creation of an interatrial communication by septostomy, or insertion of a Hickman line for continuous infusion of epoprostenol. Lung biopsy is rarely justified. The exceptions are to exclude pulmonary veno-occlusive disease, pulmonary capillary haemangiomatosis, and alveolar hypoplasia and dysplasia. It is also justified very rarely in children with complex congenitally malformed hearts in whom appropriate findings might indicate operability.

Treatment

All children with idiopathic pulmonary arterial hypertension need urgent treatment. Without treatment, the expected survival is less than 1 year.¹¹⁴ The main determinant of treatment is the response to testing with nitric oxide at cardiac catheterisation. In those with a positive response, the pressures and resistance must fall to a near normal level, with no fall in cardiac output. Only patients with a positive response can be treated with a calcium channel antagonist. This applies to less than one-tenth of the patients. Children who improve, and are stable when receiving a calcium channel antagonist, need repeated cardiac catheterisation, since they can become resistant to the drug at any time, and need escalation of therapy before they deteriorate. The majority of negative responders present in the third or fourth classes of the categorisation made by the New York Heart Association. They may need to be treated immediately with epoprostenol delivered intravenously. In some, however, it is feasible to initiate treatment with an endothelin receptor antagonist. Most children require combination therapy. Syncopal children may need an urgent atrial septostomy. After discharge from hospital, it is essential to maintain close monitoring, principally by echocardiography, since urgent intensification of therapy is frequently necessary.

The rationale for treatment is clear. Treatment with prostacyclin is indicated, in that patients with pulmonary arterial hypertension have reduced circulating levels of this agent, which is vasodilatory and prevents proliferation of smooth muscle cells relative to levels of the vasoconstrictor and proliferative compound thromboxane.¹²⁷ Clinical studies have documented an increase in expression of endothelin in the lungs of patients with pulmonary arterial hypertension,¹²⁸ and experimental studies in rats have shown that high levels of this powerful vasoconstrictor promote proliferation of smooth muscle cells and

inflammation. It is this evidence that supports the giving of antagonists of endothelin receptors. The reduced expression of nitric oxide synthase in the setting of the idiopathic pulmonary arterial hypertension also suggests that treatment with phosphodiesterase inhibitors, such as sildenafil, would be effective in dilating the pulmonary arteries.¹²⁹

Prostacyclin and Its Analogues

In the light of the above discussion, it is not surprising that the most effective therapy to date has proved to be a continuous intravenous infusion of epoprostenol, the sodium salt of prostacyclin. It has a short half-life of 3 to 5 minutes. Hence, it is unstable, and the infusion has to be prepared every 24 hours. The principal side effects are mandibular pain and diarrhoea. The child is dosed according to response. Children need much higher doses than adults. A more stable analogue of prostacyclin, treprostinil, can also be given intravenously, but is associated with more prominent side effects, such as headaches and leg pain. Meticulous care of the Hickman line is essential to prevent local and systemic infections, the latter being extremely uncommon. Treprostinil can also be given by continuous subcutaneous infusion, but this is painful, the drug stimulating neural endings, and causing induration and sometimes ulceration of the skin. Because of these problems, it is not used in children. Iloprost is another analogue of prostacyclin, which can be given by inhalation, but small and tired children find it difficult to inhale an effective dose every 2 hours. Such frequent administration is needed, since the drug is effective for less than 2 hours.

Endothelin Receptor Antagonist

The dual endothelin receptor antagonist, bosentan (Tracleer), was the first oral drug shown to be efficacious in idiopathic pulmonary arterial hypertension. It has now been used extensively in this, and other types of pulmonary hypertension, since its introduction in 2002.¹¹⁵ It is efficacious in children.^{121,122} Its principal side effect is elevation of hepatic enzymes, which necessitates a monthly blood test. Interactions can occur with other drugs, and the agent decreases effective exposure to warfarin. The newer selective antagonists sitaxentan and ambrisentan have yet to be studied in children. Both drugs affect the liver less than bosentan, and interaction with other drugs is probably less likely with ambrisentan. Clinical trials are currently still under way comparing the effects of blocking both the A and B endothelin receptor subtypes and the more selective receptor A antagonists.

Inhibitors of Phosphodiesterase

Sildenafil was the first drug of this class, and is still the most commonly used, particularly in young children with associated pulmonary hypertension. In those with the idiopathic pulmonary arterial hypertension, it is given in combination with other specific therapies. Systemic hypotension can occur when high doses are used. In babies, the dose is 0.5 to 1 mg/kg given three to four times a day, rarely more.

Anticoagulation

Patients with pulmonary vascular disease are prone to develop thrombosis. Older children are given warfarin, while younger ones usually receive aspirin. For the reasons discussed above, the international normalised ratio must be monitored particularly closely in those receiving endothelin receptor antagonists.

Oxygen

The gas is a potent pulmonary vasodilator. Nocturnal supplemental oxygen is indicated if there is nocturnal desaturation, and can benefit those with high pulmonary arterial pressures.

Atrial Septostomy

This procedure is indicated in children with idiopathic pulmonary arterial hypertension and in those with post-operative pulmonary hypertension suffering from syncope or severe right-sided cardiac failure.¹³⁰ It reduces the effect of a sudden increase in the pulmonary arterial and right-sided pressures, and maintains left ventricular output.

Lung Transplantation

Patients who fail to respond to medical therapy are offered the possibility of lung transplantation. The current predicted survival for this procedure in children is just short of 4 years, with only seven-tenths surviving at 1 year.¹³¹

New and Emerging Therapies

The therapeutic goal is to remodel the pulmonary vasculature to its normal structure, to restore endothelial function, and induce the growth of new peripheral pulmonary arteries. New modes of administration, new formulations, new analogues of existing drugs, and new antagonists of the endothelin receptors and other inhibitors are currently in development. In addition, statins, anti-growth factor drugs, inhibitors of elastase, openers of the potassium channels, stem cell and gene therapy, and inhibitors of RhoA are all under investigation. Studies showing vasodilation and reversal of pulmonary hypertension by inhibitors of Rho kinase, such as fasudil, in rodents⁷⁵ suggest that these agents should be developed for clinical use. Fasudil has indeed shown some benefit in acute testing of patients.¹³² The systemic hypotensive side effects of these agents may be reduced when the inhibitors are administered via inhalation. This issue will need to be addressed if these agents are to be useful in treating patients for a prolonged period of time. Recent attention has also focused on the vasodilator adrenomedullin and on vasoactive intestinal peptide. The latter peptide is an important vasodilator and inhibitor of proliferation of smooth muscle cells. Transgenic mice null for the peptide develop pulmonary hypertension with remodelled distal arteries. Both the haemodynamic abnormality and the pathology can be reversed with administration of the peptide.¹³³ At present, we can stabilise patients for many years, but new and radical medicines used in combination offer the hope of cure and greater promise of tailoring the treatment to the individual child. Novel therapies will emerge from improved understanding of the mechanisms initiating and maintaining pulmonary vascular disease.

Pathobiology of Pulmonary Vascular Disease

Our understanding of the pathobiology of pulmonary vascular disease has improved enormously in the past 10 years (Fig. 7-15). Studies in humans and animals have emphasised the role of three major signalling pathways. The idiopathic variant is characterised by a relative or absolute reduction in the release of prostacyclin and nitric oxide, and excessive release of endothelin. Present therapies target these three signalling pathways, singly or in combination.

Figure 7-15 The cartoon shows factors that converge in the molecular pathogenesis of pulmonary arterial hypertension, and how these may interact with BMPR2 dysfunction, a known genetic defect associated with such hypertension. The scheme focuses on factors causing increased proliferation of smooth muscle cells (SMC) and fibroblasts, as well as apoptosis of endothelial cells (EC), causing an initial reduction in vessel number, followed by proliferation of apoptosis-resistant endothelial cells in plexiform lesions. It shows multiple levels of interaction, with numerous factors related to dysfunction of BMPR2 and the Kv channels, as described in the text. For example, serotonin, hyperpolarised mitochondria, aberrant regulation of the NFATc gene, and BMPR2 dysfunction all lead to suppression or dysfunction of Kv channels. This is related to abnormal proliferation of smooth muscle cells. BMPR2 dysfunction, serotonin, and elastase all can produce increased signals from growth factor receptors. Serotonin can induce S100A4/Mts1, which also causes proliferation of smooth muscle cells, as does fractalkine. BMPR2, bone morphogenetic protein receptor 2; EGF, epidermal growth factor; EGFR, epidermal growth factor response; HHV, human herpesvirus; IL-6, interleukin-6; Kv, voltage-gated potassium channel; MCP, mast cell proteinase; MMP, metalloproteinase; NFAT, nuclear factor of activated T cells; PDGF, platelet-derived growth factor; PPAR, peroxisome proliferator-activated receptor; TGF, transforming growth factor; TNF- α , tenascin-C; TRP, transient receptor potential Ca channels.

Interestingly, clinical experience with prostacyclin preceded discovery of the scientific evidence for its use. Progress has accelerated with advances in cell and molecular biology, along with the identification of mutations in the genes for the bone morphogenetic protein receptor II, and activin-like kinase, which regulate specific signalling pathways for transforming growth factors. Exonic mutations account for half of familial and one-tenth of patients with the sporadic form of the idiopathic variant who have identifiable mutations of the bone morphogenetic protein.¹³⁴ These genetic studies have opened up new avenues for the treatment of pulmonary hypertension.

Bone Morphogenetic Protein Receptor 2

This receptor, usually described as BMPR2, is a member of the superfamily of transforming growth factor receptors. In the familial form of pulmonary arterial hypertension, the penetrance of mutations of the receptor is only about one-fifth. In other words, four-fifths of family members that carry the mutation will never develop pulmonary hypertension. The presence of a mutation is much lower, less than 10%, in patients with pulmonary hypertension acquired because of congenital left-to-right shunting.¹³⁵ Mutations have also been observed in patients with pulmonary hypertension acquired owing to ingestion of appetite suppressants, but the frequency has not been established.¹³⁶ Although the penetrance is low, the functional link between mutations and pulmonary arterial hypertension is reinforced by the fact that, independent of a mutation, all patients with the idiopathic variant have reduced expression of bone morphogenetic protein 2, as do, to some extent, patients with associated pulmonary hypertension.¹³⁷ In addition, a reduction in the expression of the coreceptor, BMPR1A, is frequently observed in patients with idiopathic pulmonary

arterial hypertension.¹³⁸ The functional consequences of a reduction, or absence, of signaling for BMPR2 in endothelial and smooth muscle cells have been addressed by a number of laboratories. When loss of the receptor is induced by interference to RNA in the endothelial cells of the pulmonary arteries, they become susceptible to apoptosis.¹³⁹ Thus, it is possible that such apoptosis is responsible for the reduction in peripheral alveolar ducts and mural arteries, causing rarefaction of the precapillary vasculature.

Loss of BMPR2 also causes proliferation of the pulmonary arterial smooth muscle cells in response to agents such as TGF- β 1 and the bone morphogenetic protein itself that normally inhibit their proliferation¹⁴⁰ and induce susceptibility to apoptosis. This observation is in keeping with the aberrant proliferative response of smooth muscle cells causing occlusive changes in the intra-acinar pulmonary arteries in patients with pulmonary hypertension. BMPR2 suppresses proliferation of smooth muscle cells in response to growth factors, such as platelet-derived growth factor, known as PDGF,¹⁴¹ and possibly others implicated in the pathobiology of pulmonary arterial hypertension, such as endothelial growth factor, or EGF.¹⁴² Signalling through BMPR2 induces differentiation of fetal lung fibroblasts into smooth muscle cells.¹⁴³ This could expand the population of fibroblasts or myofibroblasts, accounting for the adventitial and medial thickening of the hypertensive pulmonary arteries.

In view of these studies in cultured cells, it is interesting that mice with haploinsufficiency of the BMPR2¹⁴⁴ or with dominant negative receptor¹⁴⁵ develop pulmonary arterial hypertension associated with a relatively unimpressive degree of structural remodeling. This only reinforces the fact that the deficiency in the BMPR2 gene is necessary but not

sufficient to induce severe disease. Other genetic and environmental factors, therefore, need to be considered. It is still possible, nonetheless, that strategies to improve signalling through BMPR2 might be helpful, as has been shown in some rodent models¹⁴⁶ although not in others.¹⁴⁷

Also, while loss of the BMPR1A coreceptor was believed to contribute to the adverse pathology in patients with the idiopathic form of pulmonary hypertension, more recent experimental data suggest that loss of BMPR1A without concomitant reduction in BMPR2 may protect against abnormal muscularisation and loss of pulmonary arteries.¹⁴⁸ In addition, other members of the bone morphogenetic protein and TGF- β families, such as activin-like kinase type 1 and endoglin, that are mutated in hereditary hemorrhagic telangiectasia, are also occasionally mutated in patients with pulmonary arterial hypertension.¹⁴⁹ Thus, changes in the expression of BMPR2 coupled with BMPR1A, and changes in the availability of ligands that signal through these receptors, and perhaps concurrent abnormalities in downstream signalling events that influence gene expression, together with concurrent abnormalities in other members of the TGF- β superfamily of receptors, may all be required in the development of pulmonary arterial hypertension. It has been suggested that it is the loss of signals for BMPR2 that leads to an exaggeration in signals for TGF- β .¹⁵⁰ Downstream of BMPR2 signaling are the transcription factors that programme the genes important in vascular homeostasis. One such transcription factor is an inhibitor of DNA binding 1,¹⁵¹ and another appears to be PPAR γ .¹⁴¹ There is evidence from the use of cultured smooth muscle cells from pulmonary arteries that BMPR2 regulates transcriptional activity of PPAR γ ,¹⁴¹ and that apoE gene is transcribed by PPAR γ . Mice with deletion of PPAR γ or apoE develop pulmonary hypertension.¹⁵² Indeed, in the smooth muscle cells from systemic arteries, apoE can repress proliferation, preventing proliferative signals through the receptor for PDGF.¹⁵³

This is of further interest in light of work showing that repression of the PDGF receptor by imatinib can reverse monocrotaline-induced pulmonary hypertension in rats,¹⁵⁴ and may improve outcome in patients with end-stage pulmonary arterial hypertension.¹⁵⁵ In addition to apoE, other transcriptional targets of PPAR γ , such as adiponectin, can sequester PDGF,¹⁵⁶ and repress proliferation of smooth muscle cells from the pulmonary arteries. Treatment of knock-out mice for *ApoE* with the agonist of PPAR γ , rosiglitazone, increases levels of adiponectin and reverses the pulmonary arterial hypertension.¹⁵² So, it appears that, while the antiproliferative effect of BMPR2 in smooth muscle cells could be impeded in patients with a mutation there is also the potential for rescue by activating downstream effectors such as PPAR γ .

BMPR2 may also be a negative regulator of transcription factors, such as acute myelogenous leukaemia factor 1, which regulates serine elastase,¹⁵⁷ an enzyme that is also implicated in the pathobiology of pulmonary arterial hypertension. Other interesting targets of BMPR2 implicated in the proliferation of pulmonary arterial smooth muscle cells include osteoprotegerin and tenascin-C.

Elastase Activity and Pulmonary Arterial Hypertension

Previous studies analysing lung biopsy tissue from children with congenitally malformed hearts and associated pulmonary arterial hypertension suggest that elastolytic activity

may be an early feature of this complication.¹⁵⁸ Elevated activity of serine elastase was subsequently documented in the monocrotaline-induced model of disease, as well as in other rodent models.¹⁵⁹ This led to the successful experimental use of inhibitors of elastase in preventing pulmonary vascular pathology.¹⁶⁰ The mechanism relating such activity of elastase to clinical practice is also based upon studies in cultured smooth muscle cells obtained from pulmonary arteries, showing that heightened activity of serine elastase leads to the release of growth factors from the extracellular matrix, along with the activation of matrix metalloproteinases, and the induction of tenascin C, this being a glycoprotein associated with activation of growth factor receptors and survival pathways. Further studies used inhibitors of elastase not only to prevent, but to also to reverse, experimental monocrotaline-induced pulmonary hypertension by inducing apoptosis of smooth muscle cells.¹⁶¹ Regression was subsequently also achieved by blocking a downstream effector of elastase, the EGF receptor. In studies using either inhibitors or blockers, regeneration of the distal vasculature was demonstrated. Similarly, treatment with a dominant-negative construct of survivin¹⁶² was also highly successful in reversing pulmonary hypertension through apoptosis of the smooth muscle cells.

Dysfunction of Potassium Channels, Mitochondrial Abnormalities, and Pulmonary Arterial Hypertension

Recent studies have related aberrant signaling through BMPR2 to other abnormalities that are relevant to the pathobiology of pulmonary arterial hypertension. For example, reduced expression and function of voltage-gated potassium channels, notably Kv1.5, is observed in smooth muscle cells obtained from the pulmonary arteries of patients with both the idiopathic and associated pulmonary arterial hypertension, and signalling through BMPR2 has been directly related to expression of the Kv channels.¹⁶³ Reduced expression of these channels favors an influx of intracellular calcium, and promotes cellular proliferation as well as vasoconstriction. Increased expression of the voltage-gated potassium channels appears necessary in mediating the apoptosis associated BMPR2 signaling in smooth muscle cells. Agents that open the channels, like dichloroacetate, as well as gene transfer of the channels, have been used as experimental strategies in animal models to prevent and reverse pulmonary arterial hypertension.^{164,165} It is of interest that the fawn-hooded rat, which has a defect in serotonin metabolism, and develops pulmonary arterial hypertension in response to relative alveolar hypoxia at mile-high altitude, also has abnormal oxygen sensing in the mitochondria of smooth muscle cells, leading to reduced function of the Kv channels.¹⁶⁶ Reversal of the mitochondrial abnormality can be achieved through the pyruvate dehydrogenase kinase inhibitor, dichloroacetate, as described above since this reverses dysfunction of the Kv channels.¹⁶⁶ Consistent with this, it is reported that the serotonin can, in signaling through the 5HT_{2A} receptor, directly inhibit voltage-gated potassium channels in the rat.¹⁶⁷

Transient Receptor Potential Calcium Channels

Recent work has implicated expression of transient receptor potential types 3 and 6 in highly proliferating smooth muscle cells obtained from the pulmonary arteries of patients with the idiopathic form of pulmonary hypertension. These studies have shown that inhibition of these channels can repress the heightened proliferation.¹⁶⁸ Moreover,

it was also shown that inhibition of protein kinase A, or activation of cAMP, might have a similar effect.¹⁶⁹

Serotonin Receptor and Transporter and Pulmonary Arterial Hypertension

Elevated levels and transport of serotonin have been implicated in the pathology of pulmonary arterial hypertension, based upon studies in both animals and in humans.¹⁷⁰ Serotonin results in increased vasoreactivity in the fawn-hooded rat, and there is attenuated severity of pulmonary vascular disease in mice lacking the gene encoding the serotonin transporter.¹⁷¹ In contrast, overexpression of the serotonin transporter in a transgenic mouse worsens hypoxia-induced pulmonary hypertension.¹⁷² When the serotonin transporter is selectively overexpressed in the smooth muscle cells of these transgenic mice, severe pulmonary arterial hypertension ensues.¹⁷³ Moreover, haploinsufficiency of BMPR2, both in cultured smooth muscle cells from the pulmonary arteries of mice, and in transgenic mice, makes them more sensitive to the pro-proliferative effects of serotonin.¹⁷⁴ Loss of BMPR2 leads to impaired repression of PDGF-mediated proliferation of the smooth muscle cells. This disinhibition could be further compounded by increased activity of the serotonin transporter, since this also enhances PDGF receptor β -mediated signaling. Other studies have shown that serotonin-mediated stimulation of the serotonin transporter and the serotonin receptors induces cyclins¹⁷⁵ and *c-fos*, which are critical to the proliferative response of the smooth muscle cells. Serotonin also stimulates the production of S100A4/Mts1, a member of the S100 family of calcium-binding proteins.¹⁷⁶ S100A4/Mts1 stimulates proliferation and migration of smooth muscle cells,¹⁷⁶ and is increased in neointimal lesions from patients with both idiopathic pulmonary arterial hypertension and pulmonary hypertension associated with other conditions. Moreover, a mouse that overexpresses S100A4/Mts1 spontaneously rarely develops pulmonary arterial hypertension.¹⁷⁶ In one study, a gain-of-function polymorphism in the serotonin transporter characterized by two long alleles was described in two-thirds of patients with pulmonary arterial hypertension, and only one-quarter of controls.¹⁷⁷ This apparent modifier, however, was not observed in other studies with different populations of patients.

Proinflammatory State of the Vessel Wall and Pulmonary Arterial Hypertension

Increasing attention is being focused on the proinflammatory state of the vessel wall in the progression of pulmonary arterial hypertension, but the mechanisms involved remain poorly defined. The development of pulmonary hypertension in a subset of patients infected with the human immunodeficiency virus may be a function of the HLA class II alleles, such as HLA-DR6.¹⁷⁸ Also, a link was made between expression of human herpes virus-8, associated with Kaposi sarcoma, and the idiopathic variant. The mouse that overexpresses S100A4/Mts1 develops extensive and severe neointimal lesions following injection of the gamma murine herpes virus-68, this being the murine homolog of HHV-8.¹⁷⁹ The *nef* gene for the human immunodeficiency virus was also recently implicated in plexogenic pulmonary vascular lesions associated with pulmonary arterial hypertension in infected patients, and SIV-infected nonhuman primates.¹⁸⁰ Advanced occlusive lesions similar to those seen in patients with pulmonary

arterial hypertension have also been produced experimentally by an immune or inflammatory mechanism dependent on T cells following injection of soluble antigens.⁹⁵ Autoantibodies against B23, a cleavage product of a nuclear protein produced by the T-cell enzyme granzyme B, can distinguish the subset of patients with scleroderma who also have pulmonary arterial hypertension from patients with scleroderma but without hypertension.⁹⁵ Although the mechanistic significance of this biomarker is not known, in the experimental setting, haploinsufficiency of BMPR2 in mice is associated with an increase in pulmonary arterial hypertension in response to an inflammatory stimulus.⁹⁵ Other experimental models of chronic inflammation, such as repeated injections of endotoxin or TNF α , result in the development of pulmonary vascular changes. A recent study has shown that, in the model of pulmonary arterial hypertension in which loss of arteries is induced by the combination of hypoxia and SUGEN, an inhibitor of VEGF, the principal growth factor for endothelial cells, depletion of subsets of T cells worsens the pathology.¹⁸¹ This adverse response has been attributed to unbalanced activity of B cells. Heightened circulating levels of cytokines and their receptors have also been demonstrated in patients with idiopathic pulmonary hypertension, including fractalkine, and its cognate receptor, both of which are associated with heightened proliferation of smooth muscle cells. Other chemokines and cytokines, such as stromal derived factor 1 and monocyte chemoattractant protein 1, which are implicated in pulmonary arterial hypertension, have been found circulating in serum obtained from pulmonary hypertensive patients. Loss of function of BMPR2 is also known to lead to upregulation of the proinflammatory cytokine IL-6.¹⁸²

Mononuclear fibrocytes have been identified as key contributors to the remodeling of the pulmonary vasculature. It is believed that these cells, which have characteristics of both fibroblasts and leucocytes, migrate into the vessel wall through the angiomata located in the expanding adventitial layers. Heightened expression of the transcription factor NFATc2, which is associated with inflammatory cells, may also underlie pulmonary hypertension. Increased nuclear content of this factor is observed in T cells from patients with the idiopathic variant of pulmonary hypertension, and in pulmonary vascular lesions, and this can lead to repression of expression of Kv1.5 channels. The factor can be inhibited by VIVT, a specific peptide which inhibits calcineurin-mediated NFAT activation. Its nuclear translocation can be suppressed by cyclosporine. These agents can also attenuate monocrotaline-induced pulmonary hypertension.

Stem Cells in the Pathobiology and Treatment of Pulmonary Arterial Hypertension

A major effort is being directed at understanding the mechanisms underlying regeneration of the pulmonary vasculature following injury. In the mouse model of pulmonary arterial hypertension induced by monocrotaline, but not hypoxia, the recruitment of circulating stem cells appears to be protective.¹⁸³ Mesenchymal stem cells can also be engineered to prevent the development of experimental pulmonary hypertension in rodents. Mesenchymal cells have also been delivered intratracheally to attenuate the monocrotaline-induced hypertension through an obscure mechanism. In addition, these cells have been engineered to improve

myocardial performance following injection into the right ventricles in rodent models.¹⁸⁴ Endothelial progenitor cells transfected with endothelial nitric oxide synthase not only prevent, but also reverse, pulmonary arterial hypertension in rats by reestablishing connections between proximal and distal pulmonary arteries.¹⁸⁵ This strategy of genetically engineering endogenous cells to express endothelial nitric oxide synthase has been recently embarked upon in a clinical trial in patients with advanced pulmonary arterial hypertension. Non-engineered cells have been used to treat patients in a pilot study, which showed some short-term efficacy.¹⁸⁶ These results are at variance with studies indicating that these may be the very cells that induce plexiform lesions in the setting of advanced pulmonary arterial hypertension.

Right Ventricular Failure

Patients die when the subpulmonary ventricle fails. Although the focus in understanding the mechanism of pulmonary arterial hypertension has been on the small pulmonary arteries, there is evidence that changes in impedance, resulting from stiffening of the more proximal pulmonary arteries, may also be a critical determinant, not only of the pressure but also of the ability of the right ventricle to function. The right ventricle has received little attention until now, but magnetic resonance imaging gives insight into the anatomical and functional effects of a sustained increase in afterload, genetic variation may help explain patient variation in ventricular tolerance, and the molecular approaches to left ventricular dysfunction can be applied to the right ventricle. Medicinal targeting of right ventricular function demands a greater understanding of the biology of this ventricle.

PULMONARY HYPERTENSION OF VARIABLE AETIOLOGY

Pulmonary Veno-occlusive Disease and Pulmonary Capillary Haemangiomatosis

These conditions are uncommon. They can present like idiopathic pulmonary arterial hypertension, but recognition is important, because their management differs. Veno-occlusive disease usually presents with shortness of breath, sometimes accompanied by small, frequent haemoptysis. The patient may be desaturated, be clubbed, and have minimal rales on auscultation. The electrocardiogram and echocardiogram can be indistinguishable from the idiopathic variant, but the diffusing capacity is lower, and high resolution computed tomographic scans can be diagnostic to the experienced radiologist. In addition to the expected features of pulmonary hypertension, contrast computed tomography with vascular imaging shows a patchy centrilobular pattern of ground glass opacities, the lobules having the appearance of pavement because their margins are demarcated by thickened septal lines caused by oedema. Typically, mediastinal lymphadenopathy is prominent. The contrast scan also confirms the echocardiographic findings of unobstructed venous return in the large pulmonary veins. These children are usually very ill, and should be listed for transplantation without delay. Cardiac catheterisation may be indicated to confirm the diagnosis. If the child is relatively well and stable, it can be helpful to do an open lung biopsy in order to distinguish those with pulmonary capillary haemangiomatosis,

who may be amenable to treatment for a short period of time, although such treatment with anti-cancer drugs must be regarded as experimental. Pulmonary veno-occlusive disease has the distinctive pathological feature of uniform fibrotic occlusion of peripheral small veins. It can be associated with an immunopathological process. There may be extensive deposits of IgG, IgA and IgM in the subendothelial basement membranes of small veins and capillaries, but not of arteries. Deposition of IgG and complement has also been observed on capillary basement membranes in veno-occlusive disease in adulthood. Diagnosis demands immediate referral for lung transplantation.

Thromboembolic Pulmonary Hypertension

Thromboembolic pulmonary hypertension in children is usually iatrogenic, caused by intravenous hyperalimentation, catheterisation of the umbilical vein in the newborn, or a ventriculo-venous shunt for hydrocephalus. Showers of embolus discharged from the tip of the catheter can gradually occlude a large proportion of the pulmonary vascular bed. Thromboembolisation also occurs in certain hypercoagulable states, such as sickle cell disease, nephrotic syndrome, and homocystinuria.

Cor Pulmonale

Lung disease in childhood damages the airways and alveoluses while they are still developing, and may have a long-standing harmful effect on the pulmonary circulation. The most common causes of cor pulmonale in childhood are chronic long-term diseases originating at birth, and cystic fibrosis. Extensive disease of the small airways and alveoluses, as occurs in bronchiolitis, fibrosing alveolitis, and the collagen vascular disorders, can lead to pulmonary vascular change and hypertension, but this is not common in childhood. Chronic obstruction of the upper airways by large tonsils and adenoids is a well-recognised cause of pulmonary hypertension and right heart failure in children, but there is rapid improvement following surgery, and no evidence of permanent pulmonary vascular damage. Deforming thoracomusculoskeletal abnormalities, such as severe scoliosis, pleural symphysis or fibrothorax, and severe weakness of the respiratory muscles, are all recognised causes of cor pulmonale.

Congenital Abnormalities of the Lung

Pulmonary hypoplasia is associated with impaired development of airways, a reduction in the number of peripheral pulmonary arteries, and excessive muscularisation of the pulmonary arterial bed. These changes are generally present at birth. Pulmonary hypoplasia occurs most commonly in congenital diaphragmatic hernia, renal dysplasia, rhesus isoimmunisation, and more rarely, in a single lung, asphyxiating thoracic dystrophy, and phrenic nerve agenesis.^{82,83} In congenital diaphragmatic hernia, the degree of hypoplasia varies. In severe cases, there is a reduction in the number of pre-acinar airway and arterial generations, indicating that development was interrupted before the 16th week of intra-uterine life in both the affected and contralateral lung. This causes a marked reduction in total alveolar and peripheral arterial number. The lungs of babies who

survive for some time may be emphysematous, and show evidence of barotrauma caused by long-term mechanical ventilation after repair. Pulmonary hypertension is present in many babies after surgical repair, but it usually improves considerably in early life. Persistence of pulmonary hypertension can require aggressive medical therapy with antagonists of the endothelin receptors, sildenafil, and even chronic intravenous epoprostenol.

THE FUTURE

Pulmonary vascular disease is still a major problem. Important contributions from genetics, which uncover abnormalities in modifier genes of the bone morphogenetic protein pathway, will help elucidate the process by which develops idiopathic pulmonary arterial hypertension, and shed light on the mechanisms regulating susceptibility in the associated forms. The role of chronic inflammation and autoimmunity will be important to pursue in novel models that recapitulate the features seen clinically. New clinical trials based upon rescuing altered metabolism and signaling in endothelial, smooth muscle, fibroblast, and inflammatory cells should follow from findings in experimental studies.

Prevalence of Congenital Cardiac Disease

BRIAN W. McCRINDLE

Examination of the frequency of congenital cardiac disease, either as a rate or as a proportion, has important implications for the study of congenital cardiac malformations, as well as their clinical management. There is much confusion and misuse, however, regarding terminology and methodology, with important implications for the accuracy, validity and comparability of findings reported in the published literature. Knowledge of how critically to appraise these reports is important in defining their value when applied to issues of diagnostic likelihood, surveillance and trends, aetiological associations, burden of disease, and requirements for resources. These issues have more recently been impacted by fetal diagnosis and termination, with individual decisions influenced by contemporary estimates of prognosis related to the natural and modified natural history. As more patients survive into adulthood, estimates of the burden of disease, and the requirements for resources, have also achieved greater importance. The question 'how much congenital cardiac disease?' therefore continues to evolve. Providing the correct answer has important relevance for both the providers of health care, and the health care system itself.

DEFINITIONS

When considering the frequency of congenital cardiac disease, strict and explicit definitions are important, but often misunderstood and misused. Critical terms to be defined include congenital cardiac disease itself, frequency, ratio, proportion, rate, incidence, and prevalence.

In looking at reports of congenitally malformed hearts, it is important to know how the lesions were defined, and what conditions were included or excluded. Congenital cardiac disease has been defined as the presence of 'a gross structural abnormality of the heart or intrathoracic great vessels that is actually or potentially of functional significance'.¹ The additional implication of this definition is that these abnormalities arose at the time of cardiovascular development, and should therefore be present at the time of delivery or, with the advent of fetal assessment, fetal diagnosis. This definition would exclude normal variants that would be of no functional consequence, such as anomalies of the systemic veins, for example, persistent patency of the left superior caval vein, or abnormal patterns of branching of the systemic arteries that have no functional consequence. Using this definition, however, does not end all controversy. There is no current consensus as to whether several groups of

lesions should be considered to represent congenital cardiac malformations:

- Genetic conditions, obviously present from conception, which may not have manifest cardiovascular consequences until much later in life. Examples would include Marfan syndrome, Williams syndrome, hypertrophic cardiomyopathy, and pulmonary hypertension.
- Arrhythmic conditions with abnormalities at the physiologic or ultrastructural level, such as long QT syndrome and abnormal pathways producing ventricular pre-excitation pathways.
- Primary cardiomyopathies with a genetic or metabolic aetiology. This might also include myocardial abnormalities such as ventricular non-compaction.
- Structural defects which do not have functional significance in many, but not all, circumstances, such as the aortic valve with two leaflets, the prolapsing mitral valve, so-called silent persistent patency of the arterial duct or small septal defects, including patency of the oval foramen. This group might also include structural defects which resolve without ever becoming clinically manifest, such as small muscular ventricular septal defects. Consideration of these lesions is important because they are common, and might inflate a prevalence estimate.
- Persistent patency of the arterial duct in premature neonates.

Comparability of previous reports of congenital cardiac malformations has suffered from a lack of common and accepted nomenclature regarding their morphological and functional description, developmental aspects, and interrelationships. To some extent, there has been important work in consolidating nomenclature towards an internationally accepted standard.²⁻⁴ This will greatly facilitate future collection of data relevant to incidence, prevalence, and prognosis. It does not resolve the current dilemma.

RATIOS, RATES, AND PROPORTIONS

Confusion and misuse regarding the terms incidence and prevalence is rooted in misunderstanding regarding what constitutes a ratio, a rate, and a proportion. A ratio has a numerator and a denominator, which are mutually exclusive. An example would be the ratio of males to females born with transposed arterial trunks. It has use when one is interested in the relative frequencies of two related categories, and is often represented as an entity called odds. A rate has both a numerator, indicating frequency of occurrence of a condition or event, and a denominator, indicating the time period over which the numerator was accumulated. Often the rate would apply to a defined population at risk

for the condition, or an event specified in the numerator. An example would be the rate of the occurrence of a thrombotic episode in patients during their first year subsequent to construction of the Fontan circulation. Such a rate may give the impression that the condition or event occurs uniformly over the specified period of time, which may or may not be true. Rates are often used when assessing the risk of occurrence of a condition or event, and are often accompanied by explorations of factors that might be associated with increases or decreases in that rate. An often more appropriate method for looking at rates would be the calculation of Kaplan-Meier estimates, or parametric modeling of the time-related hazard, which would depict and reflect instantaneous changes in rates and risk over time. A proportion, likewise, has a numerator, which represents the frequency of a condition or category within the population specified in the denominator. It is frequently expressed as a fraction or percent, and is independent of any period of time. An example would be the proportion of patients with deficient ventricular septation in whom the defect itself is encased within the muscular ventricular septum. It would most frequently be used when describing the frequency of a characteristic or condition in a specified population.

INCIDENCE

This entity is a rate, and is strictly defined as the number of new occurrences of a condition or event identified over a specified period of time related to the number of the population at risk. The precondition is that the population at risk starts the period of observation with no occurrences of the condition or event. To apply this definition to individuals with congenitally malformed hearts, it would be necessary to begin the evaluation at conception, and then to follow embryos and fetuses throughout cardiac development to determine the number who develop defects. This would be an impossible task, since many conceptions may terminate spontaneously before cardiac development is complete, or even before conception has become manifest, or before a defect could be detected with current technology. This inability creates important challenges in the study of aetiology. Incidence and rates, however, are relevant in the study of prognosis and the natural and modified natural history.

PREVALENCE

This feature is a proportion, and is strictly defined as the number of pre-existing and new occurrences of a condition or event identified in a population at risk, either at a single point in time or over a specified period. What many mistakenly refer to as the incidence of congenital cardiac disease is in reality the prevalence, consisting of the number of newborns who are subsequently confirmed to have congenitally malformed hearts as observed within a defined population of live born individuals over a specified time. Such a proportion would more appropriately be called the prevalence at live birth. This prevalence at live birth reflects the incidence of congenital cardiac disease as modified by undetected conceptions, spontaneous and elective terminations, and stillbirths, all of which may occur differentially in those with specific aetiologies or defects.

The recognised proportion can further be modified by the completeness and accuracy of ascertainment of disease in all those neonates born alive. Rarely, some estimates of prevalence may include stillbirths, giving the prevalence of congenital cardiac disease in completed pregnancies. Alternatively, some estimates may include fetuses assessed prenatally, some of which may be spontaneously or electively terminated. If it were possible accurately to assess disease prenatally in all fetuses from a uniform time point in gestation, then it would be possible to estimate the prevalence at fetal assessment. This is not the current reality, and the current inclusion of data relating to fetal diagnosis in estimates of prevalence creates great inaccuracy and confusion.

The prevalence at live birth is, of course, important in defining the maximal burden of congenital cardiac disease in the population. The natural and modified natural history specific to certain defects, and strategies for their management, influences the changing prevalence in the population over time, with the numerator and denominator both decreasing due to deaths, and the numerator falling due to spontaneous resolution. The absolute number and characteristics of patients at any given time is important in defining the burden posed by disease, which is a key determinant in defining the requirements for resources. With the increasing survival of patients into adulthood, and their transition into the system of health care providing for adults, this number has taken on increasing importance, but its accurate estimation is fraught with numerous methodological challenges.

RELEVANCE OF INCIDENCE AND PREVALENCE

Estimates of incidence and prevalence, and the study of factors influencing them, have relevance to many aspects of congenital cardiac disease and its management.

Aetiological Associations

Accepting the caveats discussed above, it remains the case that knowledge of factors associated with variations in the prevalence of specific lesions, or groups of lesions, may suggest aetiological influences. These factors might then be used to target prenatal screening and counseling, or they might be amenable to intervention, resulting in the prevention of congenital cardiac disease. In general, studies providing evidence of such associations have been difficult to perform when using an approach depending on cohorts identified at birth, since congenital cardiac disease is rare, specific lesions even rarer, and potential factors may similarly be rare. In addition, aetiological factors may not act uniformly or consistently in respect to the lesion under investigation. Classifications of lesions on the basis of morphology may not relate to aetiology. Genetic studies have shown that specific genetic factors may be associated with a variety of lesions, which might not typically be grouped together on the basis of morphology. Studies of environmental factors have not yielded great discoveries, and have engendered few hypotheses. Focused hypotheses regarding associations between specific factors and specific lesions can more efficiently

be pursued using studies based on case-control study designs.

Surveillance and Trends over Time

Related somewhat to aetiology, there is an ongoing interest in discovering trends in the prevalence of congenital cardiac disease. Ongoing surveillance is necessary to detect acute changes in prevalence that may be attributable to a specific aetiology, such as the epidemic of birth defects associated with the use of thalidomide during pregnancy. These changes in prevalence reflect a true change in the incidence of congenital cardiac disease. Many factors other than aetiological ones, nonetheless, may contribute to a change in prevalence. Prevalence may decrease with prenatal diagnosis and elective termination. Prevalence may increase with increasing access to medical care, prenatal diagnosis, prevention of death during fetal life, improved screening and diagnostic capabilities, and their broader application. Estimates of prevalence may also change with alterations in definitions, nomenclature, and classification. Examination and comparison of prevalence across periods of time, or disparate geography and ethnic regions, requires careful attention to these details.

Likelihood of Diagnosis

Knowledge of the relative frequency of specific lesions can aid somewhat in formulating differential diagnoses and an index of suspicion. Most studies of prevalence at live birth continue to include cases that were diagnosed beyond the first few days of life, and often into the first year. In earlier studies, ascertainment relied almost exclusively on clinical manifestation and presentation. So-called critical disease is more likely to present in the neonatal period during the transition from fetal circulation with closure of the arterial duct and oval foramen, and the fall in pulmonary arterial resistance. Anomalies associated with evident syndromes are also more likely to be detected early. Some defects, such as ventricular septal defects, are not evident until further falls in pulmonary vascular resistance permit an increase in the shunting of blood, with emergence of heart murmurs and signs of cardiac failure, typically in early infancy. Still other defects, such as aortic valvar stenosis and coarctation, might initially be mild, without evident symptoms or signs, and not become manifest until the obstruction worsened weeks, months, or even years later. Some lesions, such as the aortic valve with two leaflets, or uncomplicated congenitally corrected transposition, may only present fortuitously many years later upon investigation for something else. This picture of diagnostic likelihood has changed recently. Some studies of prevalence have employed uniform early screening. Prenatal diagnosis has had an impact on age at presentation, independent of the severity or physiologic consequences of the cardiovascular defect. In addition, elective termination of more severe defects has had some impact on their relative frequency at live birth.

Burden of Disease and Requirements for Resources

Disease involving the cardiovascular system continues to be the greatest contributor to infant mortality related to congenital malformations. Trends, however, have shown significant decreases in mortality, and an increasing age at

which death might occur. The greatest attributable factor to these trends has been advances in management, which have modified the natural history. To a lesser extent, decreasing prevalence of severe lesions related to prenatal diagnosis, and elective termination, may also have an impact. These factors increase the point prevalence of congenital cardiac disease at advancing ages, and have created a growing population of adults with congenitally malformed hearts, which has been predicted soon to exceed the point prevalence during childhood. There have been no studies which have specifically quantified the point prevalence beyond infancy or early childhood. These are difficult to attain, since they would require systems providing complete capture of data, and uniform ongoing contact with those providing health care. Studies in adults would be particularly problematic, in that broad-based systems for their health care do not yet exist, and many adults lose care through lack of coverage, and lack of available providers. In addition, many adults may falsely believe that their congenital cardiac malformation has been cured when it is increasingly shown to be associated with ongoing morbidity and risk of death. Current estimates of the prevalence of congenital cardiac disease in adults rely on projections and assumptions, rather than accurate and specific collection of data. Thus, beyond infancy, the true and ongoing prevalence is poorly known, and hence knowledge concerning the burden of disease on society is equally vague. In addition, while infants and children in general maintain their contact with those providing health care, and thereby influence the estimates made for requirements of resources and future planning in a well-defined system, this is not so for adults, for whom a well-defined system of care does not yet uniformly exist. Reliable estimates of prevalence in adults based on data are needed in order to plan for, and address, their needs for health care, as well as to assess their potential impact on the overall system providing care.

METHODOLOGY AND APPRAISAL

Estimates of prevalence can vary widely between different reports, depending on how the numerator was defined and ascertained, and the source of the data for the denominator. It can also be influenced by the period of time or point in time, and the absolute numbers in both the numerator and denominator. Ideally, differences in estimates of prevalence between reports should reflect true differences in prevalence related to potential aetiological or epidemiologic factors, such as time trends or genetic or environmental differences between populations, rather than methodological discrepancies.

Denominator

When seeking to estimate prevalence, the first consideration should be the denominator, since that determines the population from which the numerator will be drawn, and also the perspective and utility of the estimate. The denominator is a key piece of information, since it defines the population to which the estimate may be applied, and suggests the population to which the estimate might be extrapolated. The most valid denominators are ones that are enumerated during the time of ascertainment of the cases, such as with a study designed on the basis of a prospective cohort. Such an approach gives the most valid and

reliable value for the denominator, and also the numerator, but is intensive in terms of both time and resources. Most estimates of prevalence use, as their denominator, the total number of live births over a specified period of time derived from a geographically defined population, hence giving the prevalence at live birth. The defined population may truly be defined by geography, or may relate to a catchment area, or to a subset of the population under a specified plan or system providing health care.

A convenient, and readily available, denominator, frequently used, is the number of births reported to a governmental system for registration of births. These almost always relate to a geographically defined population, and reporting is usually mandatory. In looking at such estimates, it should be clear that the cases were ascertained from the same catchment or geographic area as the reported number of births from the birth registry. In addition, the periods over which the births occurred, and the cases were ascertained, should be identical. Information regarding the validity and reliability of the registry should also be available. Strategies by which all births were correctly identified, characterised, and reported should be explicit. Any information regarding validation, through audits of the data, should be sought. Some registries will include stillbirths and fetal deaths, and this information should be evident. Registries of births usually collect additional information, specifically demographics for the family, but may also include data regarding clinical diagnoses and characteristics at birth. Some estimates of prevalence will rely on this information for ascertainment of cases. If so, then the validity and reliability of that data needs carefully to be scrutinised.

Some studies report the prevalence of congenital cardiac disease as a contributor to overall or infant mortality. For these studies, a governmental registry of deaths may be used to define a denominator, that being the number of deaths occurring over a specified period of time within a defined geographic area. Many of the same limitations regarding validity and reliability of data for registration at birth apply to registration at death. Information regarding clinical diagnoses and cause of death are often collected. If this is used for ascertainment, then further consideration should be given to validity and reliability, particularly since the qualifications of the persons completing and submitting these data are typically unknown, as well as the definitions they might have used.

Numerator

The numerator of any estimate of prevalence will represent the number of cases of congenital cardiac disease that were identified from a population at risk over a defined period of time. To evaluate the numerator, one must know how the cases were identified and verified from the source of the data, what types of lesions were included and excluded, and what scheme was used for nomenclature and classification.

Ascertainment of Cases

The completeness of identification of the cases from the source population is a critical aspect of appraisal of the numerator of an estimate of prevalence. A comprehensive and active prospective surveillance of all sources of cases is likely to yield the most complete ascertainment, since ascertainment is a specific and planned endeavour.

Most studies of this nature rely on clinical presentation, or evaluation of a living subject, as the initial point of entry. Many trivial lesions, nonetheless, such as small atrial septal defects, mild pulmonary valvar stenoses, tiny muscular ventricular septal defects, silent arterial ducts, and nonstenotic aortic valves with two leaflets, may not cause symptoms, and clinical findings may be subtle or absent. In addition, some of these lesions may resolve spontaneously without ever being detected. Still other types of severe lesions may occasionally lead to death before a clinical diagnosis is made or verified, and may not be ascertained unless autopsies are performed and the information is accessed and the case included. An important aspect of ascertainment is the interval from birth during which cases could be identified and included. This would be particularly important for cases identified initially on the basis of clinical features. The majority of patients with significant congenital cardiac disease would be expected to present early. Some lesions, however, may not become clinically manifest until the occurrence of physiologic changes, such as with a fall in pulmonary vascular resistance and increased shunting with ventricular septal defects, or with the development of pulmonary vascular disease or ventricular dysfunction with other lesions. Some lesions may become clinically manifest only with progression of the pathology over time, such as with valvar stenoses. The duration of follow-up for ascertainment must be sufficiently long that all cases are identified.

The optimal method for complete ascertainment would be a universal screening shortly after live birth with a technology with sufficient sensitivity to detect all lesions, usually echocardiography. Given the large number of newborns that would have to undergo screening to detect sufficient cases to allow such a valid and reliable estimate of prevalence, this is unlikely to be feasible. Currently, fetal ultrasound at 14 to 20 weeks of gestation seems to be universally performed for nearly all pregnancies in developed countries, particularly those with universal provisions for healthcare. This might afford the opportunity for a complete surveillance, but routine fetal ultrasound as performed has proven to have a low sensitivity, unless cardiac assessment is specifically and accurately applied. At present, fetal detection of cardiac lesions, even serious ones, is variable and imperfect. Other sources can be used to supplement cases ascertained from surveillance, including registries of deaths and autopsy records, registries of birth defects, and administrative data such as abstracts at discharge from hospital, and data from medical claims. These sources have the advantage that reporting is often mandatory, although they are limited by the validity and reliability with which diagnoses and details are reported.

Verification of Cases

Given the preceding discussion that most studies of prevalence rely on a clinical diagnosis for the majority of identification of cases, verification or confirmation is very important. Earlier studies focused on cases identified or verified by autopsy, but this would include only cases associated with a high mortality, and for whom a decision to perform an autopsy was made. Studies that have focused on cases ascertained through clinical presentation and identification have reported high estimates unless some sort of objective verification has been applied. Earlier studies have included cases verified by autopsy, surgery, or

cardiac catheterisation. These estimates have been somewhat low, and skewed toward more serious lesions, but become inflated when cases with a clinical diagnosis only are included. The Baltimore–Washington Infant Study was one of the first studies to include echocardiography as a means of verification.⁵ Echocardiography has since become the standard for the initial verification of cases, and has proven to have high sensitivity and specificity. In general, these early studies that used echocardiography as a means for verification have produced similar estimates to those studies which use more invasive means of verification, with larger estimates if cases with a clinical diagnosis only are also included. Broader and earlier application of echocardiography, and improved sensitivity through the application of cross sectional imaging and colour Doppler interrogation, have resulted in improved detection of haemodynamically insignificant lesions, such as tiny or small muscular ventricular septal defects, and silent arterial ducts. This improved ascertainment has largely accounted for an apparent increase in estimates of prevalence. The impact of fetal echocardiography will likely also influence ascertainment in future studies of prevalence, through both possible improved detection of cases with lesions who might succumb during fetal life, and through elective termination.

Sources of Data

Sources for the numerator vary widely in the degree to which ascertainment was passive or active, and the degree to which they accurately relate to a defined denominator. Knowledge of the details and limitations of these sources is important for critical appraisal.

Earlier studies tended to rely on registration of death and autopsy records for ascertainment. These studies were important in defining the spectrum of congenital cardiac disease and its morphologic features, particularly of complex lesions. Use of autopsy records tended to focus on cases presenting to a tertiary care centre, and were heavily weighted to more severe defects associated with a high mortality. The only valid denominator to which these cases might be applied is that of total autopsies at the given institution, and it would give the proportion of congenitally malformed hearts among deaths verified by autopsy, and may be an indicator of the contribution of congenital cardiac disease to overall mortality. Alternatively, most geopolitical regions have some sort of mandatory registration of death. There is usually an accurate enumeration of deaths, although reporting of causes of death and associated conditions may be less accurate and, therefore, less useful in determining a numerator. The accuracy of identification of cases from death certificates depends on who completes the registration, along with their knowledge of that person and their medical history, whether an autopsy was performed and the information included, and whether the congenital malformation was the primary cause of death, a contributing factor or an associated condition. One such study of death of patients with congenitally malformed hearts previously followed by paediatric cardiologists showed that only four-fifths of certificates noted cardiovascular disease, with the major defect being noted on only two-fifths of certificates.⁶ This highlights the deficiencies in relying on registries of death for ascertainment.

Secondary data is that which was collected for purposes other than the research question at hand. Usually this data is collected for purposes of documenting clinical care, such

as the health record, or for administrative purposes usually linked to reimbursement or statistical tracking. The findings often have the advantage that the collection itself is mandatory. Administrative data may include registries of births and deaths, and abstracts of discharge from hospital and databases of medical claims. The major limitation of using such data as the source of ascertainment is the variable completeness and accurateness by which diagnoses are recorded in a valid and reliable manner. Diagnoses recorded on registrations of births and deaths may only enumerate those present and verified at the time of registration. Ascertainment using databases of hospital discharges only identify those cases associated with hospitalisation, which might be true for only a limited number of lesions.⁷ The addition of databases recording medical claims that capture outpatient assessments and diagnostic testing may be important supplements to ascertainment using administrative data. While administrative data is of limited value in specifying the numerator, as mentioned previously, it is often useful in defining the denominator, particularly of live births.

An important source of secondary data for ascertainment is the medical record. Sufficient information can often be found in the medical record to identify and verify cases. Many studies have used the medical records of tertiary care centres in such a manner in reported series, but are limited in that the denominator is difficult to define. The challenge of the denominator often precludes an accurate estimate of prevalence, but these studies are useful in defining the spectrum and distribution of congenitally malformed hearts, particularly in reference to the provision of clinical care. These types of studies are now rarely reported, except from developing countries where the only cases that may be enumerated are those presenting to a specialised centre. Some studies relate to a defined system for provision of healthcare, with the denominator being all individuals captured and registered within that system. These studies can produce an estimate of prevalence, but the degree to which it is representative of the proportion of the population not included within that system is often unknown.

The most accurate and complete source for ascertainment is from surveillance, particularly if the surveillance is an active rather than passive process. Mechanisms for passive surveillance tend to rely on voluntary reporting, which may be incomplete with variable verification of diagnoses. The most valid estimates of prevalence are derived from active surveillance, particularly if both the numerator and denominator are defined simultaneously as part of the surveillance. Such active studies tend to be designed specifically to determine an estimate of prevalence. They may also include a more focused collection of data, usually in the format of case-control design, aimed at detecting associations of a potential aetiological nature. The completeness of ascertainment depends on the comprehensive nature of the system created for identification. This may include primary care networks, paediatric cardiologists working in both community-based and tertiary care practise, as well as all points of obstetrical delivery and care of the newborn. The reporting from these points of contact may be voluntary by the practitioners themselves, or may involve surveyors deployed to these sites. The reporting may occur as each case is identified, or after periodic assessments of logs or records. Identified cases are usually referred to experts for verification and specification, usually in centres of tertiary care. Pathology

departments may also be involved. Additionally, registrations of births and deaths, and other types of administrative data, may be reviewed. The challenge to complete ascertainment is the reliance on clinical presentation and findings to initiate identification and verification of the cases, the limitations of which have been stated above.

The most complete source for ascertainment would be the active screening of a defined population. A sensitive and accurate method of identification would be universally applied to all subjects included in the denominator. Clinical assessment by paediatric cardiologists has been shown to have sufficient, though not perfect, sensitivity and specificity, while other types of providers have fared less well.^{8,9} Verification and specification of clinically suspected cases with echocardiography could then be applied. Alternatively, echocardiography could be universally applied as the screening tool, ensuring complete and accurate ascertainment. These types of screenings are not feasible for application on a large scale, and the resulting estimates of prevalence would tend to be more accurate but less reliable.

Definition of Cases

Regardless of the source used for ascertainment, it must be clearly stated which specific lesions were included and excluded from the numerator. This predominately applies to lesions of minor or no functional consequence but which are common, as discussed previously. The inclusion or exclusion of these types of lesions can have an important impact on inflating the prevalence estimate. Additionally, the time period after live birth during which cases could be identified should be specified and reported. It should be clearly stated whether cases noted in stillbirths and cases diagnosed by fetal assessment, but either spontaneously or electively aborted, are included or excluded.

Nomenclature and Classification

In addition to specifying an overall prevalence, most studies provide a breakdown by specific lesions. This is challenging, in that some lesions may exist in isolation, such as partially anomalous pulmonary venous connection, or as part of a complex of lesions, such as anomalous pulmonary venous return in the setting of isomerism of the atrial appendages and complex congenital cardiac disease. Some isolated lesions may also be complicated by additional lesions, such as transposition with an associated ventricular septal defect. Some patients may have two lesions of equal importance, such as a ventricular septal defect and coarctation of the aorta. Additional lesions may be acquired as either part of the natural history, or as a result of therapeutic interventions. These distinctions make it challenging to identify primary as opposed to secondary lesions. These challenges are magnified by the lack of a uniform nomenclature. Lesions had initially been described on the basis of their first reports, such as Ebstein's malformation or the Holmes heart, and then from systematic examination of pathologic specimens. Nomenclature was therefore driven by considerations of morphology. Increasing understanding of both physiology and cardiac development have modified some of these descriptions, and have led to some controversies. As a result, individuals have used systems for description that were developed within the institutions where they had either trained or practised. Different organisations have attempted to develop consensus regarding common nomenclature, and recently have

come together as the International Nomenclature Working Group.^{2,3} This organisation seeks to cross-map the different systems, and to provide a common, consensus-based system.⁴

There is often a desire to group together lesions into categories that reflect a common basis in either development, morphology, physiology, management, outcome, or aetiology. A scheme aimed at both the presumed developmental mechanism and physiology was employed in the Baltimore–Washington Infant Study (Table 3.2 in their monograph).⁵ It was hypothesised that this classification might reduce aetiologic heterogeneity when related to potential familial and environmental risk factors. More recent studies of genetic mechanisms have shown that a single genetic defect may be associated with a more diverse range of morphologic abnormalities, and that these may not be concordant with the scheme based on developmental mechanisms. These genetic studies have refined our understanding of mechanisms of cardiac development that may influence future schemes for classification.

Reliability of Estimates

When reporting an estimate, it is important to be clear about the methodology behind determining the numerator and the denominator. When describing an estimate, details are needed of what the number represents. Prevalence at live birth is usually reported in terms of the number of cases of congenital cardiac disease in each 1000 live births. Additional information may include the geographic location, and the years over which the numerator and denominator were derived. Not all estimates made in this fashion have the same reliability. Reliability is influenced by the duration underlying the estimate, and the absolute magnitude of the numerator and denominator. Studies in which the estimate represents a period of many years are less reliable, in that changes are likely to have occurred in the system, and influenced the estimate. The absolute magnitude of the numerator and denominator influence the width of the confidence limit. A confidence limit is a statistical derivation of an interval in which we may be 95% confident, or sometimes 70% confident, that the estimate is true. The width of the interval is highly dependent on the absolute numbers. The greater the numbers, the narrower the width of the interval, and the more reliable the estimate. Confidence limits should be reported with any estimate, and often the absolute numbers for the numerator and denominator should be given. The absolute and relative magnitude of the numerator in relation to the denominator may also influence reliability. Estimates based on small numbers of cases are less reliable, and the confidence limits enclose wider ranges of relative magnitude. For example, a 95% confidence interval around an estimate of 100 per 1000 live births might be reported as 98 to 102, or $\pm 2\%$ of 100. A different study of similar size noting an estimate of 10 per 1000 live births with a similar 95% confidence interval of 8 to 12 in terms of absolute magnitude, but $\pm 20\%$ of 10 in terms of relative magnitude, thus would be less reliable. Thus, estimates for total prevalence of congenital cardiac disease, and for common specific lesions, tend to be more precise and reliable than those for less common specific lesions. In addition to reporting confidence intervals around estimates of prevalence, such intervals should

also be reported around any measure of association, such as relative risk, odds ratios, or attributable risk.

Critical Appraisal

Most studies that report estimates of prevalence are specifically designed to do so, and have it as the primary aim of the study. Before accepting the results of these studies, it is important critically to appraise the methods and reporting, in order to determine if the findings are valid, reliable, and relevant. Critical appraisal is also required when wishing to compare estimates from different studies, such as comparisons of trends over time, or different populations. Consideration must be given to all of the aspects of the denominator, numerator, and reporting already described. In Table 8-1, I have delineated questions for which the answers should be evident when critically appraising a report regarding prevalence.

FACTORS INFLUENCING ESTIMATES OF PREVALENCE

Ideally, factors should be identified that might have a true causal relationship to the development of congenital cardiac disease, and hence influence the true incidence. Other factors may alter outcomes during fetal life, and predominantly affect the prevalence at live birth. Identification of these factors may allow for the prevention of congenital cardiac disease, or provide new knowledge as to aetiology and development. The identification of these associations comes mainly from observational studies.

Environmental Factors

The most commonly held belief is that congenital cardiac disease is the product of an interaction between genes

and their environment. Evidence, however, has yet to progress sufficiently far to prove this notion. Numerous environmental factors have been linked to such development, independent of any already known genetic influence or predisposition. The Baltimore–Washington Infant Study provided a thorough assessment of environmental and parental risk factors for the development of congenital cardiac disease, and development of specific lesions.⁵ Other research has since contributed to this growing body of knowledge. It is important to note that association does not infer causality, and that identified risk factors can be viewed only as potential risk factors. To infer causality, it would be necessary to perform a randomised controlled trial, and impose a controlled exposure on mothers with child. The ethical dilemma in asking expectant mothers intentionally to expose themselves and their unborn child to a potentially harmful agent for the purposes of a randomised controlled trial can be imagined. We must rely, therefore, on observational studies. Initial associations are usually determined from studies of cohort, where exposures are determined by recall after the child has been born and identified as having congenital cardiac disease. These studies are often subject to recall bias. Case-control studies are an efficient method to focus on a specific exposure, comparing the prevalence of congenital cardiac disease in those having a specific exposure to those not confronted by the same exposure. This is usually reported as an odds ratio, being the odds of congenital cardiac disease in those with the exposure divided by the odds of the disease in those without the exposure.

A recent Scientific Statement from the American Heart Association reviewed studies of prevalence, and summarised studies of environmental factors.¹⁰ In Table 8-2, positive associations for maternal illnesses and maternal exposures are highlighted.

TABLE 8-1

QUESTIONS FOR CRITICALLY APPRAISING A REPORT ABOUT PREVALENCE

What was the stated purpose or aim of the study?

How accurate and valid was the estimate reported?

- How accurate and valid was the definition and completeness of the numerator?
 - What forms of congenital heart disease were included or excluded?
 - What nomenclature and system of classification was used to describe and group cases?
 - What were the methods by which cases were ascertained and reported?
 - What was the overall design of the study and data collection?
 - How were cases detected and reported from the population studied?
 - What factors, particularly relating to the system for healthcare, may have influenced the ascertainment of cases? Specifically, did everyone in the population studied have equal access to healthcare and the referral center, and was screening and verification influenced by differences in quality and availability of expertise or technology?
 - How were diagnoses confirmed or verified?
 - How long was the follow-up, and was it sufficiently long to capture cases with later clinical manifestation?
 - If a universal screening was applied, was it applied equally to the entire population at an early enough time point, was it sufficiently sensitive and specific, and was an assessment of verification performed?
- How accurate and valid was the definition and completeness of the denominator?
 - What was the definition of the population studied?
 - What were the sources of data used to derive the denominator, and were they valid and reliable?
 - How accurately and completely does the population studied reflect the target population or population at large?
 - Are the cases completed derived from the population studied as defined in the denominator? Were the cases and population characterized as part of the same study with the same methodology, as in a cohort study?

How reliable is the estimate of prevalence estimate? Are confidence intervals provided?

How does the estimate from the study compare to those reported from other studies with comparable methodology?

Is the estimate applicable to your own clinical population? Is the population studied similar to your own clinical population in terms of setting, time, geography, and demographic characteristics? Is the estimate of prevalence relevant to your own clinical or research question?

TABLE 8-2

FETAL EXPOSURES AND INCREASED RISK OF CONGENITAL HEART DEFECTS

Exposures Associated with Definite or Possible Risk of Offspring with Any Congenital Cardiovascular Defect	Odds Ratio
Maternal Illness	
Phenylketonuria ^{11–14}	>6
Pregestational diabetes ^{15–18}	3.1–18
Febrile illness ^{15,19–21}	1.8–2.9
Influenza ^{21,22}	2.1
Maternal rubella ²³	†
Epilepsy ²⁴	†
Prepregnancy overweight/obesity ²⁵	1.13–1.40
Maternal Therapeutic Drug Exposure	
Anticonvulsants ^{26,27}	4.2
Ibuprofen ²⁸	1.86
Sulfasalazine ²⁹	3.4
Thalidomide ³⁰	†
Trimethoprim-sulfonamide ^{*,29,31}	2.1–4.8
Vitamin A congeners/retinoids ^{*,32,33}	†

*Risk reduced if mother took folic acid simultaneously.

†Odds ratio not available.

Table 8-3 shows that maternal exposure to organic solvents has frequently and consistently been reported to be associated with relatively high odds ratios for development of specific congenital cardiac malformations. In contrast to maternal illnesses and use of medications, it is feasible to avoid exposure to organic solvents, and programmes can be directed at reducing maternal exposures to these materials.

An earlier study summarised environmental associations noted from the Baltimore–Washington Infant Study.² The study was a large population-based surveillance with careful verification. The investigators reported results as both relative risk, representing the prevalence of congenital cardiac disease in those with the exposure divided by the prevalence in those without the exposure, and attributable fraction, this being the proportion of cases of specific defects that might be attributable to specific exposure. In Table 8-4, the identified positive associations are highlighted. Some of the significant exposures were paternal rather than maternal.

Genetic Factors

The science of genetics, genomics, and proteomics has seen rapid advancements with the application of novel technologies and improved understanding. The prevalence of congenital cardiac disease is increased in children with specific chromosomal abnormalities and syndromes. Genetic defects are also being discovered that are associated with abnormalities of cardiac development and an increased prevalence. Furthermore, with increasing survival of women into the child-bearing years who themselves have congenitally malformed hearts, the issue of recurrence in the offspring has become of importance.

TABLE 8-3

MATERNAL EXPOSURE TO ORGANIC SOLVENTS AND RISK OF SPECIFIC CONGENITAL HEART DEFECTS

Defect	Risk Ratio
Defects of the ventricular outflow tracts ^{34,35}	2.0–3.9
Hypoplastic left heart syndrome ¹⁵	3.4
Coarctation of the aorta ^{15,36}	3.2
Pulmonary stenosis ¹⁵	5.0
Transposition ¹⁵	3.4
Tetralogy of Fallot ¹⁵	2.7
Totally anomalous pulmonary venous return ^{15,37}	2.0
Atrioventricular septal defect (nonchromosomal) ¹⁵	5.6
Ebstein's malformation ^{15,38}	3.6

Chromosomal Abnormalities

Children with chromosomal abnormalities have a greater likelihood of having a congenital cardiac malformation. A high prevalence of congenital cardiac disease has been observed among children with trisomy 21, or Down syndrome,³⁹ trisomy 18 or Edwards' syndrome,^{40,41} trisomy 13 or Patau's syndrome,^{40,42} and monosomy XO, or Turner's syndrome. These syndromes are also associated with an increased prevalence of extracardiac anomalies. Changes in the prevalence of these conditions as a result of elective termination on the basis of prenatal testing may influence the prevalence of congenital cardiac disease at live birth. These chromosomal abnormalities are also associated with a higher rate of fetal death and stillbirth. The median survival of live born infants with trisomy 13 is reported at 2.5 to 10 days,^{42–44} and the median survival of live born infants with trisomy 18 is reported at 2.5 to 14.5 days.^{41,43–46} Consequently, their high rate of early mortality, some of which is due to decisions to pursue only palliative care, with non-intervention, will remove them from estimates of prevalence derived at time points later in life.

The inclusion of stillbirths in estimates of prevalence is somewhat problematic, but is of importance if seeking genetic influences. Detecting the associations with congenitally malformed hearts in stillborns would require that all stillborns be autopsied and undergo genetic testing. One autopsy study found that the prevalence of congenitally malformed hearts in stillborns was 16%,⁴⁷ which is much higher than the prevalence in live born infants. Of those stillborns with congenital cardiac disease, half had more than one cardiac anomaly. The presence of a chromosomal abnormality was noted in just over half of the stillborns who had multiple or complex cardiac defects. Given the high likelihood of both congenital cardiac disease and chromosomal abnormalities in stillborns, it is, therefore, important to include them when seeking genetic associations. Likewise, inclusion of fetuses dying spontaneously prior to birth is also important, since they are also more likely to have chromosomal abnormalities in association with congenital cardiac disease. These cases, however, are difficult to capture, since abortions are usually spontaneous, and material is unlikely to be available for autopsy examination. The increasing application of fetal screening and

echocardiography will likely detect more of these fetuses, and increase the likelihood of obtaining genetic material and confirmation of diagnoses.

With the average maternal age increasing, the prevalence of infants with chromosomal abnormalities is likely to rise, in particular the number of infants with trisomy 21. This is associated with congenital cardiac disease in from two-fifths to half of pregnancies.^{48–55} After the age of 30 years, a mother's risk of having a child with trisomy 21 increases exponentially, such that by the time she is 35 years, the risk is 1 in 365 pregnancies.⁵⁶ A rate of selective termination of nine-tenths is reported when the syndrome is detected prenatally.⁵⁷ When used more routinely, prenatal screening for trisomy 21 may reduce the prevalence at birth of congenital cardiac disease associated with this chromosomal abnormality.

The prevalence at live birth of trisomy 21, trisomy 18, trisomy 13, and monosomy XO may reflect the impact of selective termination. Sensitive and specific techniques for prenatal screening that can detect these syndromes are now more readily available, especially for pregnancies deemed to

be at high risk. Parents are opting to abort affected fetuses. This is likely to influence current estimates of prevalence at live birth. Measurements of nuchal translucency, for example, have demonstrated a modest association with congenital cardiac disease.^{58,59} While not supported as an effective screening method for congenital cardiac disease,^{60,61} this method does indicate a means of identifying the possible risk for the presence of a cardiac defect, and referral for more specific screening.

Non-syndromic Genetic Abnormalities

A number of genes have been implicated in the development of congenital cardiac disease, albeit that the extent of their involvement is still relatively unknown. Studies of the influence of genetics on the development and maldevelopment of the heart are still evolving, and will be facilitated by improving technology, along with the creation of large databases and banks of tissue and deoxyribonucleic acid. Specific genetic disorders can display classic mendelian inheritance, whereby a phenotype manifests as a result of mutations in one or both copies of a gene, or they can be multi-factorial disorders, whereby a host of

polymorphisms interact with each other and environmental factors to produce a phenotype (see Chapter 9). This makes it difficult to identify the genes responsible, and their interaction with environmental factors is very complicated. Careful studies are needed to validate hypotheses regarding aetiology. Studies of prevalence, particularly those that get closest to incidence, can contribute largely to this effort.

The deletion of the 22q11 gene has been implicated as a major contributor to the development of congenital cardiac disease, as well as other major birth defects.⁶² As the occurrence of genetic testing varies from country to country, and from institution to institution, the prevalence of the deletion cannot be characterised as accurately as desired. Studies in well-defined populations have estimated the prevalence of the deletion to be around 1.5 cases in each 10,000 live births.^{62,63} It has been suggested that over 1% of all congenitally malformed hearts are associated with the deletion, accounting for half of the cases with interrupted aortic arch, one-fifth of those with common arterial trunk, and one-sixth of those with tetralogy of Fallot.⁶³

A newer body of research has begun to explore the genetics of folate metabolism and the effects on the development of congenitally malformed hearts. The methylenetetrahydrofolate reductase gene has recently been identified as playing a role in such development, with certain allelic variants having a protective effect,⁶⁴ while others are risk factors in the absence of periconceptional folate supplementation.⁶⁵

Risk of Recurrence

The risk of congenital cardiac disease recurring in the offspring of affected individuals is of increasing interest as treatment and surgical correction are allowing for survival

into adulthood, and affected women are reaching their child-bearing years (Table 8-5).

In the majority of cases, no single underlying cause can be identified. Some lesions, nonetheless, have displayed monogenic inheritance with relatively high concordance. In one study,⁹⁶ analysis was made of referrals for fetal echocardiography at a tertiary centre. When the reason for referral was a positive family history of congenital cardiac disease in a first-degree relative, the recurrence in offspring was 2.7%. In recurrent cases, the overall concordance was almost half between the parent and the first affected child for lesions in the same group, with exact concordance in almost two-fifths. Such exact concordance was high for laterality defects and isolated atrioventricular septal defects, at two-thirds and four-fifths, respectively. In one-fifth of families, first-, second-, and third-degree relatives were found to have congenital cardiac disease, providing evidence for dominantly inherited susceptibility genes with incomplete penetrance as contributors to recurrence. Supporting evidence for concordant recurrence of atrioventricular septal defect has been reported elsewhere.⁸² Of note, affected women experience more miscarriages,⁸² and congenital cardiac defects appear to occur more in the offspring of affected women than affected men,^{82,97,98} suggesting that imprinted genes play a role in normal cardiac development, relying on the maternal copy of the gene.⁸² With the population of affected adult females growing, future studies will be able to provide more information about the contribution of genetics to the development of congenitally malformed hearts. Information about these genetic influences on prevalence will accompany such findings.

Multiple Pregnancies and Reproductive Technology

It is estimated that twins of a monozygotic pair have a two-fold increase in the prevalence of congenital cardiac disease compared to singletons.⁹⁹ The prevalence of a congenital heart defect in at least one twin of a monochorionic pair is estimated at almost 1 in 10,¹⁰⁰ with the prevalence in the second twin increasing to over one-quarter if the first twin is affected.^{101,102} There is inconclusive evidence of concordancy in the lesions affecting both twins.^{100,103} Possible explanations for the increased prevalence of congenital cardiac disease in monozygotic twins include the postzygotic unequal division of the inner cell mass accounting for discordant vascular anatomy,¹⁰³ and disturbances of laterality.^{104,105} In twin-to-twin transfusion syndrome, there is a 12-fold increase in the prevalence of structural cardiac defects, possibly acquired in response to altered haemodynamics. It was reported that pulmonary stenosis accounted for one-third of the lesions present in the recipient in the setting of twin-to-twin transfusion.¹⁰³ With the increasing use of technologies for assisted reproduction, the prevalence of both monochorionic twinning and congenital cardiac disease is increasing, dependently and independently of each other. In vitro fertilisation is responsible for a prevalence of monozygotic twinning of over 3%, compared to less than 0.5% in the general population.¹⁰⁶ Multi-fetal pregnancies carry the risk of adverse neonatal outcomes resulting from premature birth,¹⁰⁷ low weight at birth,¹⁰⁷ and babies born small for their gestational age,¹⁰⁸ all of which carry associations with the development of congenital cardiac disease.¹⁰⁹ The odds ratio for a cardiovascular malformation in premature neonates has been reported to be 2.4.¹¹⁰ Studies have indicated a two- to four-fold increase in the prevalence of congenital cardiac defects in infants conceived by means of in vitro fertilisation.^{111,112} With more females delaying childbirth, and consequently seeking treatment for infertility, the potential impact on the prevalence of congenital cardiac disease might be important. Consequently, detailed fetal echocardiography is merited in the setting of multiple pregnancies, and in those resulting from in vitro fertilisation.

Systemic Factors

Two important factors are emerging as influences on the changing prevalence of congenital cardiac disease that are not reflective of changes in incidence, but of changes related to the systems providing health care. As mentioned repeatedly in the preceding discussion, prenatal diagnosis will improve ascertainment, but also allow for interventions, which may alter the prevalence at live birth. Improvements in management of most congenital cardiac lesions have led to improved survival, such that for the majority of patients, survival into adulthood is assured. This has resulted in dramatic changes in the point prevalence of congenital cardiac disease, its spectrum, and its demographics.

Fetal Diagnosis and Termination

The increasing use of fetal ultrasound and echocardiography has important implications for the prevalence of congenital cardiac disease. As I have pointed out, the true incidence of congenital cardiac disease would take into account all conceptions that are affected by a cardiac

defect. Since many fetuses may die prior to ascertainment, they are often excluded in estimates of prevalence. The impact of fetal echocardiography on prevalence, therefore, is two-fold. Detection of lesions during fetal life may allow their inclusion should the fetus die prior to birth, the cause of death never being ascertained. Of those detected through fetal echocardiography, up to one-sixth die in this fashion.^{113–115} In addition, those cases that are detected and then selectively terminated, can also be included, thus providing a higher estimate more reflective of the true incidence of congenital cardiac disease. Alternatively, cases detected during fetal life may be amenable to specific strategies for management that will prevent fetal death and stillbirth, or possibly interventions aimed at altering the development of the congenital cardiac malformation itself. At the same time, with increased use and accuracy, fetal detection is likely to increase the number of selective terminations. While these fetuses may still be counted in estimates of prevalence, information about them will have little impact on areas of antenatal and postnatal prognosis. Those cases that will be live born are of more relative importance to the systems providing healthcare than those that are terminated. Until fetal diagnosis and management is routine and clinically effective, selective termination will be an option for many parents faced with a fetal diagnosis of congenital cardiac disease, and will influence the prevalence at live birth.

Reported rates of fetal detection vary from two- to three-fifths in studies on non-selected populations,^{115–117} and may be as high as five-sixths in selected populations.¹¹⁸ Variation in detection may be attributed to the expertise of the sonographer,¹¹⁷ the stage of pregnancy at which the ultrasound is performed,¹¹⁴ and whether or not the outflow tracts are observed.¹¹⁶ During late gestation, diagnosis of lesions is easier and minor lesions are more commonly found.^{114,119} This is problematic for parents who would potentially opt for selective termination, as it is often unsafe to undergo therapeutic abortion beyond the first trimester. Lesions may go undetected if screening is performed in the first trimester. A further issue is the imperfect specificity of fetal ultrasound. A specificity of 99% would leave 1% of those referred with a false-positive diagnosis, which may lead to an unjustified termination. Reports on prevalence of terminations following prenatal diagnosis vary from less than one-fifth to half,^{113–116,120} with the majority of pregnancies being aborted in the first trimester.^{114,115} The variation is likely due to legal, social, religious, and economic factors. Termination, nonetheless, is clearly an option that parents are choosing to exercise. Some have tried to estimate the impact of fetal echocardiography on the prevalence of congenital cardiac disease at live birth.¹²¹ Assuming a sensitivity of 35%, and subsequent termination rate of 43% for an affected fetus, this would result in an estimated 15% reduction in the prevalence of the most severe forms of congenital heart defects. If diagnosis occurred earlier, termination rates would increase 1.4-fold and the prevalence at live birth would be further reduced. There is no certainty, however, that those terminations would have all been live born had the pregnancy continued.

Given that elective termination is not certain following detection of a cardiac defect, clinicians need to respond to the needs of affected fetuses for care. Awareness of a lesion during fetal life is of no value if the outcome is

no different from that of an undetected lesion presenting at live birth. Since fetal interventions are limited, and of uncertain safety and benefit, fetal diagnosis is primarily used to inform postnatal care and prognosis. For example, prenatal diagnosis is associated with a decreased risk of postnatal cardiovascular compromise and organ dysfunction, and better preoperative condition, when compared with cases diagnosed following discharge to home after hospital delivery.¹²² Delivery before 36 weeks of gestation is discouraged because of associations with high morbidity and mortality for premature neonates.¹²³ Studies of outcomes subsequent to fetal echocardiography have recently become more frequent and important, showing that anatomical and haemodynamic factors that might predict outcomes and prognosis following live birth can inform decisions relative to management both before and after live birth.^{124–129}

Adults with Congenitally Malformed Hearts

It is predicted that five-sixths of patients born with congenitally malformed hearts will now survive to adulthood. Projections suggest that this will result in the need for follow-up for over 200 extra cases per 100,000 live births each year.¹³⁰ In a representative population in 2000, there were equal numbers of children and adults alive with severe congenital cardiac disease.¹³¹ The Congenital Cardiac Centre for Adults in Toronto, Canada, reported a significant and steady fall in the mean age of their population over the period from 1987 to 1997, reflective of the number of young adults referred to their centre who had undergone previous repair as opposed to palliation.¹³² Estimates indicate that of the patients, one-quarter would have complex lesions, over half would have significant lesions, and less than one-fifth minor lesions.¹³¹ Morbidity is still relatively high in this population, especially for those with complex defects. Overall Kaplan-Meier estimates of mortality after 5 years for patients with a congenital cardiac defect after the age of 17 have been reported at 3.0% to as high as 12.6% for patients with cyanotic defects, and 8.2% for patients with those with the Fontan circulation.¹³³ The overall point prevalence of congenital cardiac disease, therefore, has and will continue to increase, with the spectrum shifting towards adults with repaired or palliated lesions. This will have an important impact on increasing the need for specialised care, with services needing to expand to meet this growing need.

With the increase in prevalence, tertiary care centres with adult congenital cardiology clinics saw increases of up to three-fold in workload between 1992 and 1997.¹³² Annual rates of hospitalisation for patients with all other congenital cardiac defects was also not inconsequential.¹³⁴ Expenditures have been reported to be higher for adults with congenitally malformed hearts than for the general population.¹³⁵ With the greater potential need for reoperation, and care during follow-up, an economic and logistical burden can be expected in the future.

REPORTED PREVALENCE OF CONGENITAL HEART DISEASE

It is unlikely that any single study will give the definitive estimate of the prevalence of congenitally malformed hearts. Studies differ in methodology and quality, as well

as the population and period of time studied. Studies using autopsy records, or series of cases gathered in clinical centres, for ascertainment do not usually report an estimate of prevalence, since the denominator is difficult to define. These studies are useful in defining the spectrum and relative proportion of specific defects. Estimates of prevalence usually come from studies where either a passive or active strategy of surveillance was used for ascertainment from a defined population.

One of the first reports was from a cardiac substudy of the Collaborative Study of Cerebral Palsy, Mental Retardation, and Other Neurological and Sensory Disorders of Infancy and Childhood, published in 1971.¹ This study prospectively enrolled pregnant mothers at 12 participating large institutions within the United States of America, and then repeatedly assessed the infants up to the age of 7 years. The study included stillbirths. Hospital and outpatient records, and autopsy reports, were reviewed for diagnoses of congenital cardiac disease. From 56,109 births, 549 cases of definite or suspected congenital cardiac disease were identified. The cases were subsequently examined by physicians involved in the study, private paediatricians, and paediatric cardiologists, and divided into three groups. The first group, of 272 cases, was made up of those with definite heart disease. The second group, comprising 222 cases, was formed by the patients initially thought to have cardiac disease, but proved to have normal hearts on evaluation. The remaining 55 cases, making up the third group, were those with signs suggestive of cardiac disease, but who did not return for evaluation. The evaluation yielded 457 cases, with 178 diagnosed at autopsy, 36 from surgical findings, 42 from cardiac catheterisation, and 201 from clinical evaluation only. This gave an estimate of prevalence of 8.1 per 1000 births. The prevalence among live births only was 7.7, but among stillbirths only was 27.5. For those live born, the prevalence among those that died before 28 days was 73.2 per 1000 deaths, and among those that died between 28 days and 1 year was 112.6 per 1000 deaths. Ventricular septal defect was the most frequent diagnosis, occurring in 133, or three-tenths, of the 457 cases.

The New England Regional Infant Cardiac Program began in 1969 with the aim of coordinating and improving the care of infants with congenital heart disease in six states in New England.¹³⁶ Medical records from hospitals and practitioners were reviewed, and data collected relative to cardiac diagnoses, procedures, and major events. The programme aimed to tabulate and report local and regional experience, with a view to improvement of quality, but information regarding prevalence and epidemiology were secondarily reported. From 1968 through 1974, 2,251 cases were ascertained, and when related to regional vital statistics of live births, gave an estimate of prevalence of 2.08 per 1000. All cases except 18 were verified by autopsy, surgery, or cardiac catheterisation. The prevalence increased from 1.82 in 1969 to 2.20 in 1974. When cases were included that had been identified only from death certificates, the prevalence increased to 2.34 in 1969 and 2.62 in 1974. Ventricular septal defects accounted for one-sixth of the cases.

A national study from Sweden used four different registries for ascertainment of those born alive with congenitally malformed hearts during 1981.¹³⁷ Of the registries,

two were involved with collecting vital statistics with mandatory reporting, namely, the Medical Birth Registry and the Registry of Death Certificates. The Medical Birth Registry of all delivery records included up to four diagnoses for the infant coded according to modified codes of the International Codes and Definitions, and added up to the time of death or discharge from hospital. The Registry of Congenital Malformations, with mandatory reporting since 1965, included cardiac defects, but only those reported within 6 months of birth, those associated with cyanosis, or cardiac failure, or death within the first week of life, and those associated with known syndromes. In 1980, a Child Cardiology Registry was established, with coordinated voluntary reporting from all five units for paediatric cardiology active in Sweden at that time. The purpose of the Registry was to provide more active surveillance, and to provide feedback to the reporting clinicians. Cases were reported if the diagnosis was made during the first year of life, with confirmation by echocardiography, cardiac catheterisation, surgery, or autopsy. Cases with isolated arterial ducts under the age of 3 months were excluded. Lesions were coded using the coding scheme of the International Society of Cardiology. Comparisons were made between the four registries regarding common cases. The Medical Birth Registry was used to define the denominator of live births. Using these sources, 853 cases were identified from 93,678 live and stillbirths, giving a prevalence at birth of 9.1 per 1000. Of the cases, however, 564 were identified only from the Medical Birth Registry data, with 75 of these being coded as suspected cardiac malformations, 2 coded as cardiac malposition, and 68 with only an arterial duct and a birth weight less than 2500 grams. Exclusion of these 145 cases gave a prevalence at birth of 7.6 per 1000. There were 17 cases that were identified from death certificates only, with 225 cases having been captured in the Child Cardiology Registry.

Perhaps the most contemporary estimate of prevalence at live birth comes from the Baltimore–Washington Infant Study.⁵ This study involved an identified cohort, and was one of the first to include echocardiography as a modality for ascertainment, verification, and classification of cases. It also prospectively defined the denominator for the cohort. From 1981 to 1989, 4390 infants with congenitally malformed hearts were identified from 906,646 regional live births, giving an estimate of prevalence of 4.84 for each 1000 live births, with 95% confidence limits from 4.70 to 4.99. The prevalence increased throughout the period of study, with the proportion of cases having diagnostic confirmation by echocardiography increasing, and those confirmed by cardiac catheterisation decreasing. The prevalence in the last 3 years of the study was 5.5 for each 1000 live births. The overwhelming contributor to the apparent increase in prevalence was an increase in the number of perimembranous and muscular ventricular septal defects, reflecting better ascertainment with increasing use of and improvements in echocardiography. Ventricular septal defects accounted for one-third of the cases (Table 8-6).

The Baltimore–Washington Infant Study included a case-control study within its design, with control infants randomly selected each year of the study from all live born infants without congenitally malformed hearts in a manner stratified by the hospital managing the births.

TABLE 8-6

DISTRIBUTION OF DIAGNOSTIC GROUPS IN ORDER OF FREQUENCY (N = 4390)

Diagnostic Group	Number	Percent (%)
Ventricular septal defect	1411	32.1
Pulmonary stenosis	395	9.0
Atrial septal defect within oval fossa	340	7.7
Atrioventricular septal defect	326	7.4
Tetralogy of Fallot	297	6.8
Transposition	208	4.7
Coarctation of aorta	203	4.6
Hypoplastic left heart syndrome	167	3.8
Aortic stenosis	128	2.9
Patent arterial duct	104	2.4
Isomerism of atrial appendages	99	2.3
Double outlet right ventricle	86	2.0
Bifoliate aortic valve	84	1.9
Cardiomyopathy	82	1.9
Pulmonary atresia with intact septum	73	1.7
Peripheral pulmonary arterial stenosis	65	1.5
Totally anomalous pulmonary venous return	60	1.4
Common arterial trunk	51	1.2
Congenitally corrected transposition	47	1.1
Ebstein's malformation	43	1.0
Tricuspid atresia	32	0.7
Interrupted aortic arch	31	0.7
Other left-sided lesions*	26	0.6
Double inlet ventricle	18	0.4
Other right-sided lesions†	9	0.2
Divided left atrium	5	0.1

*Includes 13 cases of coronary arterial anomalies, 7 anomalies of the aortic arch, 5 instances of mitral valvar regurgitation, and 1 case with drainage of the superior caval vein to the left atrium.

†Includes eight examples of partially anomalous pulmonary venous return and one pulmonary arterial sling.

From Ferencz C, Rubin JD, Loffredo CA, Magee CA: Epidemiology of Congenital Heart Disease: The Baltimore–Washington Infant Study: 1981–1989, Vol 4. Mount Kisco, NY: Futura, 1993.

A comprehensive questionnaire was completed by standardised interviews of mothers at home visits. The questionnaire collected data regarding demographic, maternal health, nutritional, genetic, and environmental factors. The study defined a broad spectrum of familial and genetic factors, which were present in just over one-third of cases. Table 8-7 gives the results of a multi-variable analysis of potential risk factors without inclusion of maternal reproductive history variables. When the number of previous pregnancies is included in the model, three or more pregnancies, as opposed to none, has an adjusted odds ratio of 1.29, and maternal age, race, familial noncardiac malformations, local contraceptives, and increasing number of drugs taken are no longer significantly associated with congenital cardiac disease. When associations with environmental risk factors were examined separately for cases with and without genetic risk factors in comparison to controls without genetic risk factors, a greater number of environmental risk factors with stronger associations were noted in the analysis of cases with genetic risk factors, particularly for exposures to therapeutic drugs. This suggests that environmental factors have a greater influence in those with an underlying genetic susceptibility.

TABLE 8-7

MULTI-VARIABLE MODEL OF POTENTIAL RISK FACTORS WITHOUT MATERNAL REPRODUCTIVE HISTORY VARIABLES

Variable	Adjusted Odds Ratio*	95% CI
Genetic Factors in Nuclear Family		
Familial congenital heart disease	2.20	1.69–2.85

From Ferencz C, Rubin JD, Loffredo CA, Magee CA: Epidemiology of Congenital Heart Disease: The Baltimore–Washington Infant Study: 1981–1989, Vol 4. Mount Kisco, New York: Futura, 1993.

A large-scale study using a universal screening strategy for ascertainment has yet to be performed. Investigators from Japan performed a more focussed screening of newborns with echocardiography aimed at determining the prevalence and natural history of muscular ventricular septal defects, a lesion known to inflate estimates of prevalence.¹³⁸ They screened 1028 newborns delivered at term without evident chromosomal abnormalities, and identified 21 newborns with muscular ventricular septal defects, 3 with coarctation of the aorta, and 1 with double outlet right ventricle, giving a prevalence of 24.3 cases per 1000 live births. The 95% confidence limits were wide, ranging from 15.8 to 35.7, and thus the estimate is not very reliable given the relatively small number of subjects. Only three-fifths of the ventricular septal defects were associated with a cardiac murmur, and follow-up showed that three-quarters had closed spontaneously by the age of 12 months, with the majority closing before 6 months. This has implications for strategies of ascertainment that rely on clinical presentation for identification. If diagnostic confirmation is delayed, many defects will have closed spontaneously, and escape verification.

Two teams of reviewers have examined multiple studies of prevalence with an aim of comparing, and potentially pooling, the estimates. The investigators from the Baltimore–Washington Infant Study compared their prevalence at live birth from their initial 2 years of the study, 1981 and 1982, to that of eight previously published and widely cited reports.¹³⁹ The prevalence from the Baltimore–Washington Infant Study for that period was 3.7 cases for each 1000 live births, with all cases being confirmed by autopsy, surgery, cardiac catheterisation, or echocardiography. The studies differed widely by dates, number, and characteristics of the population of births, time period after birth during which cases were accrued, and methods of ascertainment, verification, and classification. The New England Regional Infant Cardiac Program spanned 1969 to 1977, with 2251 cases of congenitally malformed hearts ascertained from follow-up up to 1 year after birth for 1,528,686 resident live births from six New England states in the United States.¹³⁶ Cases were verified by autopsy, surgery, or cardiac catheterisation, with a prevalence of 2.03.

When cases verified only by echocardiography were excluded from the estimate of prevalence made from the Baltimore–Washington Infant Study, their estimate became more similar, at 2.38. The remaining seven studies included cases for which a clinical diagnosis without verification had been made, varying from three-tenths of half of included cases, with estimates ranging from 5.51 to 8.56.^{1,137,140–144} If cases that were diagnosed by clinical means only were excluded from these estimates, the prevalence then ranged from 3.75 to 4.30, which is comparable to the estimate reported by the investigators conducting the Baltimore–Washington Infant Study. The review also compared the prevalence of specific defects, and noted wider variations between studies.

A more recent review provided an analysis of a larger number of studies, with an aim at determining the sources of variability in estimates of prevalence between studies.¹⁴⁵ This analysis was based on review of 62 studies reported after 1955, with larger studies representing surveillance registries or cohort studies, and smaller studies usually from less developed countries representing series of cases reported from clinical centres which were based on larger geographic population-based denominators. Wide discrepancies were found in reported estimates of prevalence, ranging from 4 to 50 per 1000 live births (Fig. 8-1). Estimates were stable, at between about 4 and 8 for each 1000 live births, until 1985. The advent of widespread use of echocardiography at this point resulted in estimates becoming more diverse, and the reported prevalences began to exceed 10 for each 1000 live births (Fig. 8-2). The increases in overall estimates of prevalence reflected an overall increase in ascertained cases, but this was more marked for trivial or mild lesions, particularly ventricular septal defects, with the estimated prevalence of lesions producing cyanotic disease remaining relatively stable (Fig. 8-3). The estimated prevalence of ventricular septal defects is reflective of the modality used for ascertainment and verification, but also on the timing, since more complete early ascertainment would be expected to capture more lesions which would subsequently undergo spontaneous closure. The median prevalence of congenital heart disease was 7.7, with an interquartile range from 6.0 to 10.6, excluding nonstenotic aortic valves with two leaflets, silent arterial ducts,

and isolated partially anomalous pulmonary venous connections. The median prevalence of bifoliate aortic valves was 9.2, with an interquartile range from 5.3 to 13.8. Inclusion of cases with such bifoliate aortic valves would greatly inflate estimates of prevalence. The median

prevalence of congenitally malformed hearts producing cyanosis was 1.08, with an interquartile range of 1.27 to 1.53. In Table 8-8, I have summarised the statistics regarding the prevalence of specific lesions for each one million live births.

Figure 8-1 Histogram of the prevalence of congenital cardiac defects per 1000 live births, as noted in 62 reports. (From Hoffman JI, Kaplan S: The incidence of congenital heart disease. *J Am Coll Cardiol* 2002;39:1890-1900.)

Figure 8-2 Changes in the reported prevalence of congenital heart disease (CHD) from multiple reports over time, and the influence of the proportion of ascertained cases of ventricular septal defect (VSD). Each circle represents the value derived from each report. The horizontal lines are drawn arbitrarily at a prevalence of 10/1000 live births and 40% of all congenital heart disease, and the vertical lines are drawn arbitrarily at 1985 and 40%, respectively. An increasing proportion of the high prevalence estimates are beyond 1985 and for series that have over 40% ventricular septal defects. (From Hoffman JI, Kaplan S: The incidence of congenital heart disease. *J Am Coll Cardiol* 2002;39:1890-1900.)

Figure 8-3 The association of the reported prevalence of ventricular septal defects to total, total exclusive of ventricular septal defects, and cyanotic cardiac disease, as assessed from reported studies. Abbreviations as in Figure 8-2. (From Hoffman JI, Kaplan S: The incidence of congenital heart disease. *J Am Coll Cardiol* 2002;39:1890-1900.)

This is an important monograph providing the full results of the seminal active surveillance study incorporating echocardiography, with a case-control comparison regarding potential risk factors. The prevalence was 4.84 per 1000 live births.

- Hiraishi S, Agata Y, Nowatari M, et al: Incidence and natural course of trabecular ventricular septal defect: Two-dimensional echocardiography and color Doppler flow imaging study. *J Pediatr* 1992;120:409–415.

This study universally screened 1028 newborns with echocardiography, and identified 21 with muscular ventricular septal defects, with four additional cases of congenital cardiac disease. Early screening of live births gives the highest estimates of prevalence through complete ascertainment of cases.

Aetiology of Congenital Cardiac Disease

BENOIT G. BRUNEAU, JOHN BURN, and DEEPAK SRIVASTAVA

Perhaps one of the most vexing aspects of congenital cardiac disease is the current inability to explain its origin. Environmental causes have been invoked, and until recently only scant evidence had pointed towards a genetic component. Recent experimental data, combined with advances in human genetics, have now provided a clearer understanding of how some malformations may occur, and certainly have illuminated general concepts that are certain to apply to congenital cardiac disease in general. One of the most important developments has been the paradigm shift from grouping lesions based on clinical presentation, to understanding the anomalies based on their embryonic and genetic origins. Thus, it is now clear how an inherited mutation can result in a family where one individual has an interatrial communication, while another tetralogy of Fallot, and still be considered the same genetic defect. In this chapter, we will review the various aetiologies, environmental and genetic, with a constant eye towards the embryology of the heart, with the hope that by synthesising the current knowledge, we will provide a useful insight into the fundamental basis of congenital cardiac malformations.

EPIDEMIOLOGY OF HEART DISEASE: GENES VERSUS ENVIRONMENT

The study of the aetiology of congenital cardiac disease initially focused on epidemiological studies, which mainly incorporated the identification of factors that influence the incidence of the various lesions. This is in large part because familial inheritance is not obvious, and thus a tractable focus is environmental influence and assessment of heritability. These studies primarily led to the conclusion that there were multi-factorial influences. Several difficulties are apparent with these studies. First, intra-uterine mortality due to congenital cardiac disease is difficult to assess, and conversely, in addition to the nearly 1% of children with cardiac malformations,¹ an additional 1% to 2% of the population harbour more subtle cardiac developmental anomalies that only become apparent later in life. Second, familial associations are rarely obvious. In retrospect, this should be evident from the observations that defined mutations in a single gene can cause seemingly unrelated lesions, compounded by forme fruste or low genetic penetration.

Amongst epidemiological studies, the Baltimore-Washington Infant Study was a prospective surveillance for liveborn cases from 1981 to 1989, with a case-control study to determine aetiological associations.^{2,3} More than

4000 cases were identified amongst close to 1 million live births. Some clues about inheritance were obtained,²⁻⁴ but despite suggestive information, the focus of genetic evaluation was on chromosomal anomalies and known hereditary syndromes, and not on identification of specific mutations. Thus, although several teratogenic causes of heart defects have been documented, their underlying causes are unknown. Most recently, prenatal use of angiotensin converting enzyme has been identified as a strong risk factor for congenital defects that include cardiac lesions.⁵

Other than obvious associations with chromosomal syndromes, such as atrioventricular septal defects in the setting of Down syndrome, genetic causes have been slow in their discovery and characterisation. Some cardiac conditions have a clear familial component, and include Marfan's syndrome, Williams syndrome, and Holt-Oram syndrome.^{6,7} Recognition of the syndrome produced by deletion of chromosome 22q11 has caused a paradigm shift in how clinicians now think about the genetic contribution to congenital cardiac malformations.^{8,9} The deletion syndrome is associated with a host of cardiac lesions, ranging in severity, and mostly involving the ventricular outflow tracts.^{7,9} The deletion has been reported in up to three-fifths of those with interrupted aortic arch, one-third of those with common arterial trunk, one-sixth of those with tetralogy of Fallot, and one-tenth of patients with ventricular septal defect. Routine testing is now standard, although its influence on cardiac outcomes is as yet unclear. It is interesting to note that the identification of the most likely causative gene came from studies in the mouse.¹⁰⁻¹²

In contrast to clearly defined syndromes, most congenital cardiac malformations rarely occur in families with a sufficient number of affected members to lend themselves to genetic linkage analyses. Also, when familial cases occur, they are often marked by heterogeneity of defect, and affected family members may manifest as cardiomyopathy or arrhythmia rather than congenital malformations. Decreased penetrance and variable expressivity also occur, and suggest that additional environmental and genetic factors may contribute to risk of malformation. Historically, therefore, the risk factors for reoccurrence of the lesions were based on epidemiological studies such as those described above, and were classified broadly into family inheritance and vague environmental considerations. More recently, genetic analyses have determined that even some common types of defects have a genetic component. For example, atrial septal defects, and aortic valves with two

leaflets, have been shown to be inheritable.^{13,14} The subsequent isolation of the causative genetic mutations substantiated this notion.^{15–17}

CARDIAC DEVELOPMENT: KEY CONCEPTS

While early anatomical descriptions have provided significant insights into normal cardiac development, modern genetic experimentation with model organisms has been particularly useful in deciphering the anatomical and genetic contortions that the developing heart must undergo to become a formed and functional organ. It has become clear that the genetic pathways that operate in such diverse species as the fruitfly, zebrafish, and mouse are relevant to each other and provide important biological insights that are relevant to human disease. In particular, the fruitfly and the zebrafish have permitted the discovery of previously unknown pathways due to their use in large-scale phenotypic-based screens for discovery of genes. Similarly, genetic manipulation in the laboratory mouse, whose cardiovascular system is nearly identical to that of humans, has allowed profound insight into the mechanisms underlying human disease.

Origins of the Heart

The vertebrate heart arises from paired pools of mesodermal precursors. Cardiac differentiation begins shortly after gastrulation has begun, and the first clear markers of the differentiating heart are apparent near the end of gastrulation, this occurring during the eighth day of development in the mouse. The process demarcates a horseshoe-shaped group of cells called the cardiac crescent (see also Chapter 3). These cells will contribute to the atria and left ventricle, while another group of cells more medial within the cardiac crescent will form the so-called second heart field, or lineage, from which the right ventricle, outflow tract, and a portion of the atria will be derived.^{18–24} The cells of the cardiac crescent come together at the midline of the embryos, where their fusion and anterior growth leads to the formation of the linear heart tube. This beating structure breaks the symmetry of the embryo, and loops towards the right side as distinct chambers form during the ninth day in the mouse. Looping proceeds during the tenth day, with growth of distinct chambers, giving rise to a heart composed of left and right atria and ventricles. Subsequent steps in cardiac morphogenesis refine the distinctions between each chamber, and separate the left and right sides by growth of septa.

A recent discovery is that the outflow tract, the right ventricle, and a large component of the atria arise not from cardiac crescent-derived myocardium, but from a population of cardiac cells that form more anteriorly—the so-called second heart field.^{20–23,25–27} As defined by genetic lineage analysis, the second field originates very early in development from mesoderm expressing the transcription factor *Isl1*. This lies near the area of the heart-forming mesoderm and is displaced cranially during development of the embryo. A subset of this area itself, initially called the anterior heart field, is marked by the presence of *Fgf10* and *Mef2c* mRNA.^{21,26}

This remarkable discovery has fundamentally altered our view of cardiac morphogenesis. Instead of continued

growth of a defined population of differentiated cells, uncommitted cardioblasts from the second lineage are actively recruited into the heart, where they differentiate into cardiac cells. In fact, *Isl1*-expressing precursor cells have been shown to persist postnatally as cardiac myoblasts.²⁸ The discovery of the second lineage is also significant from the stance of a disease. To understand lesions involving the outflow tract and right ventricle, we must understand how the factors that regulate their formation from their precursors are coordinated and integrated with the rest of the heart. In DiGeorge syndrome, the defective gene operates primarily in the second lineage, affecting its differentiation and migration.^{29,30} Thus, understanding of how the switch in lineage occurs from undifferentiated myoblasts from the second field to differentiated cardiac myocytes has many implications for embryology and disease.

The lineage of the second field has also been shown to be a multi-potent precursor cell, which can give rise to all cardiovascular cell types, including myocytes, endothelial cells, and smooth muscle of the vasculature.^{31–33} These multi-potent cells differentiate into the three different cell types presumably in response to local cues, such as growth factors, which instruct a particular gene programme to be activated over another. Additionally, these cardiovascular precursors restrict their potential as they further differentiate. This is a strategy similar to that employed by haematopoietic precursors, which give rise to the different cell types that form blood.

The primary heart field was initially thought to contribute to the entire heart. Although no lineage analysis has been performed, it appears that it is the left ventricle and part of the atria that derive from the primary field. Some evidence for this comes from deletion of *Tbx5*, which is largely absent from the second field and its derivatives.^{34,35} Loss of *Tbx5* in the mouse results in severe hypoplasia of the caudal segment of the heart, the atria and left ventricle, leaving intact the right ventricle and outflow tract.³⁵ Unlike the complete absence of derivatives of the second field in *Isl1* knock-out mice, *Tbx5* mutant mice still develop primitive, albeit malformed, structures. Mutations in other genes that affect formation of the heart most severely do not affect early formation of the tube from the first heart field.^{23,35–37} The determinants of the so-called primary heart field, and the importance of its differentiation for overall cardiac development, are not known.

Genes That Regulate Formation of the Heart

Beginning with the discovery of the *tinman* mutant in *Drosophila* in 1989, several dozen genes have been identified that are critical for various aspects of formation of the heart, from its earliest inception, through major morphogenetic steps, and into postnatal regulation of cardiac function. Most genes encode transcriptional regulators, which turn on or off other genes, or signalling molecules that activate potent intracellular signalling cascades.

Transcription Factors

The fruitfly *tinman* mutation was identified in flies that did not form any heart at all, the mutation being named after the character in *The Wizard of Oz*.³⁸ This mutation was in a gene belonging to a family of transcription factors called

the homeodomain factors. Shortly after this discovery, vertebrate versions were identified, which were given the less colourful name of *Nkx2-5*. It turns out that *Nkx2-5* in vertebrates is not essential in itself for formation of the heart, but it does have important functions in early initiation of the cardiac genetic programme, and in formation of the cardiac chambers.^{39,40} As will be discussed below, along with many other genes that were initially experimentally defined, *NKX2-5* is one of the genes that has been identified as causative in inherited human congenitally malformed hearts.¹⁵ Considerable literature exists on the function of *Nkx2-5*, and in many of its functions it interacts with other transcription factors that are important for the normal development of the heart. For example, a factor from another gene family, *Gata4*, also plays important roles in heart differentiation, in chamber morphogenesis, and also has additional roles in bringing the two heart fields together. The last role was dramatically evident from its mutation in the mouse, which led to production of a bifid heart.^{41,42} And as with *NKX2-5*, human genetics has pinpointed *GATA4* as a gene that when mutated causes inherited congenital cardiac defects. The primary role of *Nkx2-5* in the developing heart is to activate a set of target genes that will execute the correct cellular differentiation program of a variety of types of cells. For example, certain contractile protein genes rely on *Nkx2-5* for their initial activation, and the proper development of the conduction system relies on its appropriate function.

Gata4, as mentioned above, is also a key player in formation of the heart. Indeed, this gene has been shown to be important for such diverse aspects of formation as early differentiation, valvar formation, chamber maturation, and even postnatal function. In fact these same roles have also been ascribed, to varying degrees, to *Nkx2-5*. Genes that are active in the early heart usually have binding sites for *Gata4* and *Nkx2-5* in the regulatory regions, called enhancers, that confer cardiac-specific expression of genes. *Gata4* and *Nkx2-5* function together to act on these sequences of enhancers, and this interaction provides a degree of robustness and specificity to the system. Many other transcription factors have been defined as important for various aspects of cardiac formation. They often have multiple roles at various times during development, reflecting their potency and versatility.

Growth Factors

Growth factors of many different families are important for several aspects of heart development. In early development, the bone morphogenic factors and the *Wnts*, two types of developmentally important secreted factors, are key inducers of cardiac development, via their instructive cues that promote expansion of early cardiovascular precursors, and later also the induction of cardiac differentiation from these same precursors.^{43–49} The picture is a bit more complicated, as some *Wnt* signals also dampen cardiogenesis, by slowing the growth of precursors, presumably so that the timing of cardiac differentiation is kept.^{43–48,50}

Growth factors are also important in later stages of cardiac development, such as valvar formation and septation.⁵¹ Bone morphogenetic proteins are critical for the initiation of the earliest steps in valvar formation, and indeed the dosage of *Bmp4*, for example, results in valvar

malformations and deficient atrioventricular septation that are reminiscent of human disease.^{52,53} Later regulation of valvar morphogenesis relies on a complex interplay between myocardium and endocardium which is regulated by calcineurin-dependent signalling and the repression of vascular endothelial growth factor in myocardium of the valve-forming region.⁵⁴

MicroRNA Regulation of Cardiac Development

The transcriptional regulation of cardiac development and its modulatory and instructive signalling pathways are well studied, and their biology is becoming well understood. Less clear is the translational control of cardiac morphogenesis by small noncoding RNAs, such as microRNAs. MicroRNAs are genomically encoded 20- to 22-nucleotide RNAs that function by targeting mRNAs either for translational inhibition or for degradation, leading to an effective reduction in quantity of the protein product. Several hundred human microRNAs have been identified, and some of these have important roles in development that may be eminently relevant to congenitally malformed hearts.

The best characterised example is the microRNA-1 family, comprising *miR-1-1* and *miR-1-2*. These microRNAs are highly conserved from worms to humans, and are specifically expressed in the progenitor cells of developing cardiac and skeletal muscle as they differentiate.⁵⁵ Both are highly expressed in the cells of the outflow tract derived from the second heart field. Interestingly, expression of these microRNAs is directly controlled by well-studied transcriptional regulatory networks that promote muscular differentiation. Cardiac expression is dependent on serum response factor, and expression in skeletal muscle requires the myogenic transcription factors MyoD and Mef2. Consistent with a role in differentiation, overexpression of *miR-1* in the developing mouse heart results in a decrease in expansion of ventricular myocytes, with fewer proliferating cardiomyocytes remaining in the cell cycle. Validation of *Hand2* as a target for *miR-1* suggests that tight regulation of levels of protein may be involved in controlling the balance between cardiomyocyte proliferation and differentiation. *miR-1* and another microRNA, *miR-133a*, are transcribed in a polycistronic message, therefore sharing common regulation, and both are co-expressed in cardiac and skeletal muscle. As in cardiac muscle, *miR-1* promotes the differentiation of skeletal myoblasts in culture, but interestingly, *miR-133a* has the opposite effect, inhibiting differentiation and promoting the proliferation of myoblasts.

Defects caused by mutations in microRNA genes range from benign to severe. Disruption of the single fly orthologue of *miR-1* had catastrophic consequences, resulting in uniform lethality at embryonic or larval stages, with a frequent defect in maintaining cardiac gene expression.⁵⁶ In a subset of flies lacking *miR-1*, a severe defect of cardiac progenitor cell differentiation provided loss-of-function evidence that *miR-1* was involved in events leading to muscular differentiation, events, similar to the gain-of-function findings in mice. *miR-1* in flies regulates the Notch signalling pathway by directly targeting microRNA of the Notch ligand, Delta,⁵⁶ potentially explaining the involvement of *miR-1* in deriving differentiated cardiac cells from an equivalency group of progenitor cells. Thus, *miR-1* seems to be a muscle-specific microRNA that directs progenitor cells

towards a cardiac cell fate by regulating central mediators of determination and differentiation. Although only three miRNAs have been deleted in mice to date, targeted deletion of miR-1-2 resulted in ventricular septal defects, although with incomplete penetrance.⁵⁷ In surviving adults, disruption of normal cardiac conduction and cell cycle control was also observed.

Haemodynamics and Formation of the Heart

As the heart forms, it soon begins to beat and pump blood. This occurs at the early stages of cardiac looping, well before chambers have formed and separations between segments of the heart are established. It would seem intuitive that the physical forces of a beating heart would affect its morphological development, but until recently this has been but a concept. In fact, haemodynamic forces are indeed important, and shape not only the normal development of the heart, but produce the secondary defects associated with major structural congenital cardiac malformations.

The initial identification of a role for haemodynamics was in zebrafish, a simple model of cardiac development in which a single atrium connects to a single ventricle. By altering the flow at the inflow or outflow of the zebrafish heart, and imaging the structure and function of the heart, it was determined that altering flow within the heart led to abnormal cardiac looping and defects in formation of the cardiac cushions, indicating that normal intracardiac flow is a key regulator of cardiac morphogenesis.⁵⁸ This was confirmed using zebrafish and mouse models in which embryonic contractility is impaired or absent.^{59–61} More recent experiments, again in zebrafish, have clearly shown that intrinsic defects in contractility of cardiac myocytes, in combination with external haemodynamic forces, are essential for the normal development of the heart.⁶²

The most intriguing results on haemodynamics and cardiac development have a direct connection to congenital malformations. It had been observed in a mouse model of laterality defects that include anomalies of the outflow tracts that formation of the arteries in the brachial arches is randomised between the left and right sides.⁶³ Normally, the arches form initially in bilateral fashion, but the left-sided brachiocephalic artery regresses, leaving only a right-sided artery. It was determined that, in this mouse model, the flow to the brachial arches was randomised to both left and right sides, unlike the usual situation where flow is preferentially directed to the right side. With a combination of surgical and morphological manipulations, it was shown that the altered flow was the likely culprit for the abnormal presence of a left-sided brachiocephalic artery. Thus a genetic defect, in this case involving *Pitx2*, not only leads to direct defects in regions of the heart where the mutated gene is expressed, but produces morphological defects secondary to altered flow. This finding has important implications for the understanding of the origin of congenital cardiac malformations.

CHROMOSOMAL DISORDERS

Each body cell contains, in its nucleus, 46 chromosomes. This is its own copy of the blueprint for the body. Of these, 44 chromosomes are common to males and females. These are the 22 pairs of autosomes. The remaining two are the

sex chromosomes, X and Y. Aneuploidy is a generic term for any disturbance of the chromosomal complement other than the addition of whole extra sets, which represents polyploidy. Translated literally, aneuploidy means 'not good set' and may be defined as the loss or gain of all or part of a chromosome.

Autosomal Aneuploidy

Autosomal aneuploidy, that is, any disturbances of chromosomes other than X or Y, causes major disturbances of embryonic development, with the result that most afflicted fetuses are spontaneously aborted. Among the survivors, the most common form of aneuploidy is trisomy. This is the addition of one whole extra chromosome. Most cases are the result of non-disjunction at meiosis. When the primordial cell divides to produce an egg or sperm, the matching pairs of chromosomes separate so that the gamete contains one of each. This makes 23 in all, and this is known as a haploid set. The fusion of an egg and sperm restores the number to 46. If a pair of chromosomes fails to separate at meiosis, the gamete, and hence the embryo, will have either one too many, or one too few. The latter group abort, as do most of the former, particularly when large chromosomes are involved. Fetuses with trisomy for the smaller chromosomes may reach term, in particular those with trisomy 13, 18, or 21.

Trisomy 21

Of children born with a cardiac defect, 1 in 20 has trisomy 21.⁶⁴ It is, therefore, the largest specific aetiological category. Intelligence is rarely in the normal range, the mean quotient being about 50. Such children have an increased incidence of malformation and disease, including duodenal atresia, Hirschsprung's disease and anal atresia, leukaemia, and defects of the immune system. Those who reach adulthood tend to age prematurely. Of particular interest here is the frequency of cardiac malformations. In a large review of infants with trisomy 21 who had a cardiac defect, just over two-fifths were found to have an atrioventricular septal defect, while three-tenths had multiple anomalies, with persistence of the arterial duct being the second most common lesion, afflicting one-sixth.⁶⁵ Review of a necropsy series showed that almost half of infants with Down syndrome had a cardiac malformation, with two-thirds having an atrioventricular septal defect.⁶⁶ The strong association of atrioventricular septal defect with trisomy 21 is not seen with other chromosomal anomalies. It prompts the speculation that some important function of growth or adhesion of the endocardial cushions is determined by genes on the chromosome 21, or else abnormal genes disturb the separation of the common muscular atrioventricular junction, since it is the common junction which is the hallmark of the malformation. From a practical viewpoint, the presence of left-axis deviation in a neonate with the features of Down syndrome makes an atrioventricular septal defect very likely.

Mosaic Down Syndrome

About 3% of children with trisomy 21 have a parent who is a mosaic. This means that some of the parental cells have an extra chromosome 21, and this involved one or both

gonads. If mosaicism is identified in the parent, the recurrence risk is greater than 10%.⁶⁷ It is the existence of such families that accounts for part of the 1% recurrence risk in siblings of a child with trisomy 21. In addition, some parents seem to have an increased risk of non-disjunction, since recurrences of trisomy involving chromosomes other than 21 have been described.

Trisomy 18, or Edward's Syndrome

Trisomy 18 affects 1 in 3500 newborns. Early death is almost invariable because of the multiple malformations. Survivors are severely developmentally delayed. Typical features are a prominent occiput, low-set malformed ears, and a small jaw, though the appearance is less characteristic than that seen with trisomy 21 or 13. Two additional clinical signs of great value are the unusual clenched fists, and rocker bottom feet. Cardiac defects are present in the majority, most being persistent patency of the arterial duct or ventricular septal defects. A bedside diagnosis is strengthened by examination of dermatoglyphic patterns.

Trisomy 13, or Patau's Syndrome

One in 7000 newborn infants has Patau's syndrome. The majority die as neonates. Survival beyond the first year is exceptional. The characteristic clinical features are polydactyly, cleft lip and palate, often bilateral and severe, and hypotelorism associated with malformation of the frontal lobes of the brain, also known as holoprosencephaly. There is a high incidence of cardiac defects, in particular atrial and ventricular septal defects. Abnormalities of cardiac position are relatively frequent,⁶⁸ perhaps indicating isomerism of the atrial appendages. As with atrioventricular septal defects and trisomy 21, the high incidence of disturbed cardiac position in trisomy 13 may reflect a specific role for this part of the genome in the determination of laterality.

Aneuploidy of the Sex Chromosomes

The female has two X chromosomes in each cell. The male has one X and the small Y chromosome. The latter determines maleness. The normal development of males shows that only a single copy is required for genes on the X chromosome. Females avoid having an excess by inactivating one of the two X chromosomes in each cell between the 16- and 1000-cell stages of embryonic life, a process called lyonisation. When excess of X chromosomes is present in each cell, all but one are switched off. An embryo, therefore, can tolerate chromosomal complements that contain three, four, or five X chromosomes with relatively little disturbance of development. Apart from the frequent occurrence of persistent patency of the arterial duct in the group with five X chromosomes, cardiac development is not affected. This is not the case when a single sex chromosome is present from the start, as in the 45, X karyotype.

45, X, or Turner's Syndrome

Though first described by Ullrich, the resultant syndrome is associated with the name of the American physician Turner. Despite being mild relative to most other forms

of chromosomal aneuploidy, Turner's syndrome is associated with particularly heavy prenatal loss. Based on studies of aborted fetuses, it is estimated that the frequency of 1 in 10,000 births represents only 1% of conceptions with the 45, X karyotype.⁶⁹ Failure of sexual maturation, and short stature, are associated often with a webbed neck, also known as *pterygium colli*. Other features are a shark mouth, down-slanting palpebral fissures, and low-set ears. The strong association with aortic coarctation is well known. Aortic stenosis is the most common of a wide variety of other cardiac defects seen rarely in patients with Turner's syndrome. The prevalence of cardiac defects among 45, X individuals is estimated between 10% and 20%.⁷⁰

SYNDROMES INVOLVING MICRODELETIONS: SINGLE GENES OR MORE?

22q11 Microdeletion Syndrome (DiGeorge Syndrome) and Defects of the Outflow Tracts

By far the most important example of a microdeletion is 22q11 deletion. About 3 million base pairs are normally lost in this disorder, resulting in the loss of at least 30 genes. There are segments at either end of the commonly deleted segment that have the same sequence. At meiosis, when the two copies of chromosomes 22 pair, this repeat makes them liable to misalign. If a crossover then occurs, it is possible to produce a chromosome with this segment deleted.

All individuals with this syndrome have facial features, though these may be subtle. Typically those involved will have short and narrow palpebral fissures, which may be up-slanting, a bulbous tip to the nose, which seems pinched because the supporting facial structures are flattened, a small mouth, and small rounded ears. While several acronyms have been utilised to describe this genetic disease, including Shprintzen syndrome, velo-cardio-facial syndrome, conotruncal anomaly face or Takao syndrome, Strong syndrome, and CATCH22, the most descriptive and inclusive name is 22q11 microdeletion syndrome.

A broad range of congenital cardiac malformations are seen in the setting of 22q11 microdeletion syndrome, including tetralogy of Fallot with pulmonary stenosis or atresia, common arterial trunk, and interrupted aortic arch. This range of lesions, in addition to the extracardiac defects found in the syndrome, made it difficult to pinpoint a particular causative gene or group of genes in the minimal 22q11 interval solely based on their known or perceived function. It took clever mouse chromosome engineering studies to pinpoint the likely single gene responsible for the majority of defects in 22q11 microdeletion syndrome. Taking advantage of the similar arrangement of genes between mouse and human, known as synteny, researchers utilised the power of mouse genetics to mimic the 22q11 microdeletion.^{71,72} Once this rather spectacular technological feat had been achieved, the same groups refined their analysis to whittle down the interval, in effect doing in mouse what nature had not quite done in humans. These studies, combined with additional mouse models, narrowed down the likely culprit for the majority of defects in 22q11 microdeletion syndrome to a gene for a transcription factor, *Tbx1*.^{10,11} *Tbx1* encodes a transcription factor that had previously

not been functionally characterised, but is a member of the developmentally important T-box gene family. Significant debate surrounded this discovery, as it was considered unlikely that a single gene in the 22q11 minimal interval would result in all the defects in the syndrome, and confounding data from deletions that excluded the minimal interval, and therefore *TBX1*, further fueled the debate. The potential for *TBX1* as a major causative gene was strongly supported by the identification of *TBX1* missense mutations in patients with features of 22q11 microdeletion syndrome, but without a microdeletion.⁷³ Again, mouse genetics has lent support for the possibility that other genes within the 22q11 critical region probably also contribute to the disease, as deficiency of the 22q11 gene *crkl* results in similar defect in a mouse model and exacerbates loss of *Tbx1*.^{74,75}

Although the congenital cardiac malformations seen in the setting of 22q11 microdeletion syndrome were attributed based on inferences to defects in migration of cells from the neural crest migration, *Tbx1* is expressed in the second heart field, and is important for its normal expansion.^{29,30} The transcription factor *Tbx1* appears to affect the neighbouring cells in the neural crest in a non-cell autonomous fashion by promoting secretion of fibroblast growth factor that interacts with its receptor on the cells from the neural crest to affect their proliferation or differentiation.

Williams Syndrome and Supravalvar Aortic Stenosis

The association between supravalvar aortic stenosis and the classic dysmorphic pattern known as Williams syndrome has been established in the literature for many years.⁷⁶ It led to speculation that there might be a gene responsible for the cardiac defect that was deleted as part of a microdeletion syndrome. This proved to be correct. Unlike the usual progression from deletion to discovery of the gene, the process was reversed when a patient with supravalvar aortic stenosis caused by a translocation focused attention on the elastin gene carried on chromosome 7.^{77,78} Fluorescent in situ hybridisation soon revealed microdeletions in patients with Williams syndrome. Elastin is a major component of the walls of large vessels, and disruption of this gene somehow leads to excessive proliferation of cells in the vascular wall in mice.^{79,80} The mechanism by which elastin regulates cellular proliferation is currently unknown. There is continuing controversy about the underlying cause of the characteristic learning disability with the outgoing personality. The chromosomal basis of the recurrent deletion appears to be a set of inversions that promotes recombination.⁸¹

Alagille Syndrome and Peripheral Pulmonary Arterial Stenosis

Peripheral pulmonary arterial stenosis is the hallmark of Alagille syndrome, a multi-system disorder affecting liver, cardiovascular system, spine, eyes, and face. The association of a microdeletion involving chromosome 20p12 narrowed the region of interest and led to identification of the causative gene defect, loss of *JAGGED1*.⁸² Mutations in this gene, which encodes a Notch receptor, cause cardiac

defects, not only in the context of Alagille syndrome, but also in isolated cases of congenital cardiac disease.^{82–84} This gene encodes a ligand for the Notch family of receptors. The Notch pathway is involved in control of a variety of processes, extending from tissue patterning and morphogenesis to cancer. This discovery explains, at a superficial level, the stenotic lesions in the pulmonary vascular tree, along with the other features of the syndrome, such as hypoplasia of the biliary ductules, posterior embryotoxon of the eye, butterfly vertebrae, and the characteristic face. Much work will be needed to understand fully the relationship between the genetic error and the clinical phenotype, but the discovery of the loss of *JAGGED1* focuses attention on the correct pathway. Furthermore, the observation that loss of the whole gene produces the same phenotypic spectrum as mutations within the gene that lead to a gene product of reduced size demonstrates that this is a haploinsufficiency syndrome. In other words, the problem arises from loss of half of the gene product.

Defects of Laterality

Defects of laterality are often associated with congenital cardiac lesions, specifically those associated with isomerism of the atrial appendages, or visceral heterotaxy (see Chapter 22). The genetic cascades that regulate the situs of internal organs, including the lateralisation of the atrial appendages, have been carefully delineated using experimental models.⁸⁵ As defects of laterality in humans can be inherited, it is likely that in many cases single gene mutations are responsible. Indeed, human genetic studies have identified mutations in a few genes that lead to inherited defects of laterality.⁸⁵ A search for mutations in these genes in patients with congenital cardiac lesions but in the absence of isomerism that did not have any other feature of laterality defects identified a few rare cases, indicating that they may be a cause of isolated disease.^{86,87}

SINGLE GENE DEFECTS

In the last decade, human genetic studies have identified several genes that are mutated in those with inherited cardiac disease. All of these are important regulators of cardiac morphogenesis, supporting the concept that the cardiac malformations are primarily a disease of abnormal embryonic organogenesis. These findings have also cemented the notion that most lesions have a genetic origin. In addition, these discoveries have clearly demonstrated that unrelated lesions can be caused by the same genetic defect, resulting in a need to reexamine epidemiological studies from a different perspective. In all cases, the mutations are dominant, as they affect only one of two alleles of the gene. As yet, it is not known how dominant mutations in these genes result in profound aberrations in formation of the heart. They may be related to decreased dosage, or may be due to gain of function effects. It is of paramount importance to understand the molecular consequences of disease-causing mutations, and the mechanism underlying these events, in order to be able to design in rational fashion non-surgical therapeutic interventions for those with congenitally malformed hearts. The future of our understanding of the aetiology of the lesions, therefore, lies in understanding how

mutations in these important regulators leads to altered morphogenesis.

Syndromic Mutations

Mutations of *TBX5* in Holt-Oram Syndrome

Some genetic mutations have been identified in rare syndromes that include congenital cardiac malformations. For example, mutations in *TBX5* cause defects in the context of Holt-Oram syndrome.^{88–90} These defects are predominantly interatrial communications, usually within the oval fossa, muscular ventricular septal defects, and abnormalities of the conduction system, but mutations can also result in more diverse abnormalities, such as hypoplastic left heart syndrome, totally anomalous pulmonary venous connection, and common atrioventricular junction (Fig. 9-1). The syndrome also includes defects in limb formation, specifically of the radial ray, the thumb, first digit, and radius. Most defects of the limbs involve the thumbs, and range in severity from mild triphalangeal thumbs, up to complete phocomelia, with defects of intermediate severity such as missing thumbs, and hypoplastic radius.

Mutations have been found throughout the *TBX5* gene,⁹⁰ although they predominantly cluster in the so-called T-box domain, which confers DNA-binding capabilities on the protein. Early studies supported the concept of genotype-phenotype correlation, whereby mutations in one part of the gene were predominantly associated with families with severe cardiac defects, while mutations in a different part of the gene were found in families that had a predominance of severe limb, but not cardiac, defects.⁹¹ Subsequent findings, however, discounted this hypothesis. It is now believed that the difference in manifestation of disease is more likely a result of genetic background.^{90,92,93}

The observation by clinical geneticists that limb anomalies often coincide with cardiac defects has led some investigators to investigate *TBX5* mutations for several related disorders. This often does not yield positive correlations.

Recent work has strived to define the clinical criterion for the Holt-Oram syndrome in relation to the presence of *TBX5* mutations. Indeed, there is excellent concordance, as long as a strict definition is maintained for the components of the syndrome.⁹⁴

Modelling of Holt-Oram syndrome in the mouse has revealed interesting and important features of the consequences of haploinsufficiency on downstream target gene regulation.^{35,95,96} In particular, it is clear that some genes in the heart are exquisitely sensitive to the dosage of *Tbx5*, explaining the occasional severity of defects in mice or humans with reduced dosage of this gene. Some genes, such as the gap junction protein-encoding gene *Gja5*, also known as connexin 40, are targets that may explain some aspects of Holt-Oram syndrome, such as, in this case, the atrioventricular block. In other cases investigation of the mouse model has led to the intriguing observation that independent of structural lesions one can identify clear defects in diastolic function due to reduced *Tbx5* activity. These functional deficits are directly due to reduced function of the calcium pump (see Chapter 4), related to reduced activity of the *Serca2a* gene, which is directly regulated by *Tbx5*.⁹⁶ These results, observed in the mouse, correlate to human patients with Holt-Oram syndrome, indicating that specific defects in cardiac function can accompany structural lesions while being unrelated to them except for their underlying genetic cause.⁹⁶

Mutations of *SALL4* in Okamoto Syndrome

Mutations in the Spalt gene *SALL4* have been found to underlie Okamoto syndrome, which, as with Holt-Oram syndrome, affects the limbs as well as the heart, although it also has a broad spectrum of ocular, renal, and other defects.^{93,97–101} The two syndromes are sometimes confused clinically due to very similar defects involving the heart and limbs, but molecular genetic studies have clearly outlined the distinction between the two.⁹³ Using mouse models, it has been shown that *Sall4* and *Tbx5* genetically and

Figure 9-1 *Tbx5* expression and congenital heart defects in Holt-Oram syndrome. **A**, In situ hybridisation of *Tbx5* (red signal) in an E13.5 mouse embryo, with expression in the atria (la, ra), left ventricle (lv) and left side of the interventricular septum, and right ventricular (rv) trabeculae. **B**, A diagrammatic representation of *Tbx5* expression in a mature heart, and the location and type of congenital heart defects found in Holt-Oram syndrome patients. Numbers in parentheses represent numbers of reported cases. AA, aortic atresia; ASD, atrial septal defect; CSD, conduction system defects; DORV, double outlet right ventricle; ECD, atrioventricular septal defect with common atrioventricular junction; HLH, hypoplastic left heart; LA, left atrium; MVP, mitral valve prolapse; PAA, pulmonary arterial atresia; PDA, persistent patency of arterial duct; PLSVC, persistent left superior caval vein; TA, tricuspid atresia; TAPVR, total anomalous pulmonary venous return; TF, tetralogy of Fallot; TRA, common arterial trunk; TRAB, trabecular anomalies; VSD, ventricular septal defects. (Adapted from Bruneau BG: The developing heart and congenital heart defects: A make or break situation. Clin Genet 2003;63:252–261; and Bruneau BG, Logan M, Davis N, et al: Chamber-specific cardiac expression of *Tbx5* and heart defects in Holt-Oram syndrome. Dev Biol 1999;211:100–108.)

physically interact to pattern the heart and limbs,¹⁰² thus explaining the reason for the similarities in syndromes caused by mutations in either gene.

Disruptions of the RAS Signalling Network in Noonan's Syndrome

Autosomal dominant gain of function mutations in *PTPN11*, encoding the protein tyrosine phosphatase SHP2, cause Noonan's syndrome, characterised by pulmonary stenosis, hypertrophic cardiomyopathy, and occasional atrioventricular valvar defects.¹⁰³ Most recently, hypomorphic mutations in *SOS1*, an essential RAS guanine nucleotide-exchange factor (Ras-Gef), was shown to enhance RAS-ERK activation, and this can account for as high as one-fifth of the cases of Noonan's syndrome not explained by *PTPN11* mutations.^{104,105} Recent evidence implicates epidermal growth factor signalling as an important regulator of late valvar remodeling. Loss or attenuation of EGFR/ErbB1 signalling results in preferential hypercellularity of arterial but not atrioventricular valves.¹⁰⁶ The hyperplastic arterial valvar phenotype is augmented when crossed to mice heterozygous for a null mutation in *ptpn11*.¹⁰⁷ Deletion of the EGF ligand, heparin binding epidermal growth factor, results in increased size of the endocardial cushions and ridges, along with the size and proliferation of cells in both the arterial and atrioventricular valvar leaflets.^{108,109}

Non-Syndromic Mutations

Mutations of *NKX2-5* Cause Septation and Other Defects

Mutations in the *NKX2-5* gene cause defects similar to those caused by mutations of *TBX5*, namely deficiencies of atrial and ventricular septation, problems with conduction, hypoplasia of the left heart, and others anomalies such as tetralogy of Fallot or Ebstein's malformation.^{15,110–112}

Mutations were originally identified in two families with very distinctive clinical features, namely progressive atrioventricular block in the setting of interatrial communications. Subsequent studies showed that this unusual combination was not the only type of lesion that could be caused by the mutations. Indeed, mutations in *NKX2-5* were identified in several additional families that had some members presenting with an interatrial communication and atrioventricular block, but others with ventricular septal defects in isolation, Ebstein's malformation, and tetralogy of Fallot¹¹⁰ (Fig. 9-2). These results were extended to sporadic cases, which in addition to several cases of interatrial communication within the oval fossa and tetralogy of Fallot, included rare sporadic cases of common arterial trunk, double outlet right ventricle, congenitally corrected transposition, interrupted aortic arch, hypoplastic left heart syndrome, and aortic coarctation.¹¹² This was perhaps not surprising to developmental biologists, who would expect a broad set of defects based on the pancreatic expression of the *Nkx2-5* gene in the mouse, but it showed with definitive clarity that a single defined mutation could result in a wide range of clinically and anatomically unrelated defects. This finding went a long way to explain the considerable difficulties in identifying familial inheritance of congenital cardiac malformations.

As with mutations of *TBX5*, a broad range of mutations have been identified in the *NKX2-5* gene, which is made up of two rather compact exons. Functional analysis of these mutations has determined that, for the most part, mutations of *NKX2-5* result in a loss of activity for the gene, whether it be due to the production of a truncated protein, or one that cannot activate transcription by itself, or one that does not allow the gene to interact with its partner proteins such as *TBX5* and *GATA4*.^{113,114} The biochemical basis of the differential expressivity of the various *NKX2-5* mutations, therefore, has not been elucidated, and we are left once again with the potential for genetic modifiers as the modulating factors.

Figure 9-2 *NKX2-5* mutations cause a variety of inherited congenital cardiac malformations. Four family trees are shown, each representing a discrete mutation in *NKX2-5* that when inherited is associated with a range of defects, including atrioventricular block (AV block), atrial septal defects (ASD), ventricular septal defects (VSD), and tricuspid valvar abnormality (TV abnormality). Circles represent females, squares represent males. Roman numerals indicate generations within a family. (Adapted from Benson DW, Silberbach GM, Kavanaugh-McHugh A, et al: Mutations in the cardiac transcription factor *NKX2.5* affect diverse cardiac developmental pathways. *J Clin Invest* 1999;104:1567–1573.)

The progressive nature of the atrioventricular block in some patients with mutations of *NKX2-5* was an important clue about one of its unexpected roles in the heart. From a clinical standpoint, this discovery suggests that patients with the familial form of atrial septal defect should be followed longitudinally to check for the appearance of problems with atrioventricular conduction even after surgical correction of the septal defect. Indeed, studies in the mouse have suggested that a primary defect in the conduction system is at the root of these problems with conduction, and that additionally the loss of *Nkx2-5* might lead to cardiomyopathy unrelated to the structural defects or the abnormalities in the conduction system.¹¹⁵

Mutations of *GATA4* Cause Problems with Septation

Families have now been identified with problems in septation as a their sole phenotype. Genetic mapping in two unrelated families with interatrial and interventricular communications have identified mutations in *GATA4*¹⁶ (Fig. 9-3). These mutations were predicted to result in a partial loss of function of the gene, and also predicted impaired interaction with *Tbx5*, thus linking the function of these two transcription factors to septation of the atrial and ventricular chambers. Mutations in *GATA4* have also been identified in a few other families and individuals,^{116,117} but overall they are rare in patients with congenitally malformed hearts. Mouse models previously would not have predicted that dominant mutations in *GATA4* could cause congenital cardiac disease, as mice heterozygous for *Gata4* null alleles were normal. Recent results have shown that, when bred in a particular strain, loss of one copy of *Gata4*

does indeed result in significant congenital cardiac disease, which resembles to a certain degree the malformations seen in humans with mutations of *GATA4*.¹¹⁷

Mutations of *NOTCH1* Cause Bicuspid Aortic Valve

Malformations of the valves are due to improper valvogenesis, and can vary in severity. As such, they may not be recognised until adulthood, when the valves begin to malfunction. The most common cause of valvar disease is seen in patients with aortic valves having two instead of three leaflets, the so-called bicuspid aortic valve. Found with a prevalence of 1% to 2% in the population, it is the most common congenital cardiac anomaly, affecting more patients than all other defects combined. The bifoliate valve can cause disease in childhood if the valvar abnormality is severe, and can be part of the hypoplastic left heart syndrome. Indeed, one-sixth of first-degree relatives with hypoplasia of the left heart have bifoliate aortic valves not necessarily producing symptoms, suggesting a common genetic aetiology. The bifoliate aortic valve is more frequently asymptomatic until later decades of life, when premature calcification, prolapse, or bacterial endocarditis occurs. In those with calcification or regurgitation, the valve becomes stenotic, leading to dysfunction that eventually requires valvar replacement. This disease is the third most common form of cardiac disease seen in adults, and over 50,000 bifoliate aortic valves are replaced annually in the United States of America alone.

Recently, through investigation of families with autosomal dominant disease, mutations in *NOTCH1* were identified as a genetic cause of the valvar malformations and calcification.¹⁷ Linkage studies mapped the disease

Figure 9-3 *GATA4* mutations cause septal defects. Family A is a five-generation kindred with several family members afflicted with congenital malformations of the heart, as listed in the table to the right of the family tree. Family B has inherited defects across four generations; defects are again listed in the table to the right of the family tree. In both families, affected members with a plus sign carry a *GATA4* mutation. An echocardiogram of one patient shows atrial and ventricular septal defects. AR, aortic regurgitation; ASD, atrial septal defect; AVSD, atrioventricular septal defect; LA, left atrium; LV, left ventricle; PS, pulmonary stenosis; PDA, patent arterial duct; RA, right atrium; RV, right ventricle; VSD, ventricular septal defect. (Adapted from Garg V, Kathiriyala IS, Barnes R, et al: *GATA4* mutations cause human congenital heart defects and reveal an interaction with *TBX5*. Nature 2003;424:443-447.)

locus to mutations in *NOTCH1* in two unrelated families with a similar valvar phenotype (Fig. 9-4), specifically severe premature calcification of a bifoliate valve. Interestingly, a subset of family members who harboured mutations in *NOTCH1* had trifoliate aortic valves, but still developed calcification that required subsequent valvar

replacement. Thus, *NOTCH1* signalling may be required to suppress calcification of the mesenchymal cells of the valve under normal circumstances. Indeed, experimental studies showed that *NOTCH1* represses the osteoblast phenotype that is typical of valvar and vascular calcification. As for other familial disease, a wide spectrum of lesions was observed within family members, including tetralogy of Fallot, hypoplasia of the left heart, and ventricular septal defect, likely due to genetic background features.

CONCLUSIONS

So far the clinical impact of the identification of genetic mutations producing congenitally malformed hearts has not been felt, largely because of an incomplete understanding of the range of mutations and their functional significance. In some cases, pre-implantation in vitro fertilisation genetic screening has been established for those mutations that cause very severe defects.¹¹⁸ Clearly, a comprehensive genomics-based examination of a much larger set of genes in a wide range of patients is required to begin to understand the genetic basis for congenital cardiac malformations.

Congenital cardiac disease, therefore, can now be conceived as not only a defect of morphogenesis, but in some cases, a failure of differentiation among subsets of lineages that contribute to the heart. We are now embarking on a phase in which knowledge of developmental pathways, and high-throughput methods of genotyping rare and common genetic variants, should allow rigorous investigation into the causes of human cardiac disease. With the increasing recognition that congenitally malformed hearts harbour a significant genetic contribution (Table 9-1), we can now imagine that genetic variation underlies both the morphogenetic defect, and the predisposition to long-term consequences that will affect clinical outcomes for the millions of survivors. Thus, vigorous efforts to identify genetic variation associated with the congenitally malformed heart, and outcomes of treatment, will be essential as therapeutic or preventive measures to alter the course of disease may be possible throughout childhood and in the adult. It may even be conceivable eventually to predict genetic risk among parents, and focus preventive strategies on those at greatest risk vertically to transmit the disease. The efficacy of folic acid in prevention of defects of the neural tube provides hope for similar prevention of congenital cardiac disease.

Figure 9-4 *NOTCH1* mutations cause aortic valvar disease associated with more severe congenital cardiac malformations. Family A and Family B both have inherited *NOTCH1* mutations (indicated by the plus signs). Most patients in both families have bicuspid aortic valve, but several members also have more severe defects, such as aortic stenosis (AS), hypoplastic left heart syndrome (HLHS), mitral stenosis (MS), ventricular septal defect (VSD), or tetralogy of Fallot (TOF). One patient has both mitral stenosis and a ventricular septal defect. (Adapted from Garg V, Muth AN, Ransom JE, et al: Mutations in *NOTCH1* cause aortic valve disease. *Nature* 2005;437:270–274.)

FREQUENCY OF GENETIC MUTATION IN HUMAN CONGENITAL CARDIAC DISEASE

Gene Name	CHD	Numbers of Families/% CHD Population	Reference
BMPR2	PPH + CHD (ASD, VSD, AVSD)	6% (6/106 PPH + CHD cases)	119
CFC1	TGA	2% (2/86 TGA cases)	87, 120
GATA4	ASD, VSD	Five families/12% (2/16 ASD cases)	16, 121, 122
NKX2-5	ASD, AV block, TOF, Ebstein's	4% of ASDs and 4% TOF; 3/16 ASD	110–112, 121
NOTCH1	BAV, TOF, AS, VSD, HLHS, IAA	Two families	17
THRAP2	TGA	One family/3% (3/97 TGA cases)	123
ZIC3	CHD	2% (2/97 non-heterotaxy CHDs)	124

AS, aortic stenosis; ASD, atrial septal defect; AVSD, atrioventricular septal defect; AV block, atrioventricular block; BAV, bifoliate aortic valve; CHD, congenital heart disease; HLHS, hypoplastic left heart syndrome; IAA, interrupted aortic arch; PPH, pulmonary hypertension; TGA, transposition; TOF, tetralogy of Fallot; VSD, ventricular septal defect.

In this paper, the aetiology of Noonan's syndrome was identified in the form of mutations that affect the function of an important signalling molecule.

Fetal Echocardiography

ANITA L. SZWAST and JACK RYCHIK

Malformations of the heart and arterial trunks are the most common form of congenital anomalies found in humans. They occur in approximately 6 of every 1000 live births, and in 8 to 10 of every 1000 pregnancies. Fetal echocardiography, or the use of ultrasonic technologies to evaluate the fetal cardiovascular system, enables diagnosis of structural heart defects, and offers a way to observe complex physiological processes prior to birth. The primary benefits of fetal echocardiography include the ability to counsel parents prior to birth as to the expectations for a child born with a congenitally malformed heart, the ability to implement appropriate postnatal management strategies in an anticipatory fashion, so as to maximise outcome, and the ability to identify and treat cardiovascular diseases prior to birth.

SCREENING WITH FETAL ECHOCARDIOGRAPHY

As imaging technologies, and the skills of operators, continue to improve, a higher percentage of congenital cardiac malformations can be detected accurately before birth. Analysis of large registries has shown that rates of detection can vary from 15% to 25%.¹⁻⁵ Many studies have documented the utility of the four-chamber view of the heart in identifying the malformations during fetal life.⁵⁻¹¹ In these studies, rates of detection using this view alone ranged from 4.5% to 81%.⁵⁻¹¹ Malformations of the outflow tracts, however, and discordant ventriculo-arterial connections, may frequently be missed when this view is used in isolation. When views showing the right and left ventricular outflow tracts are included in the obstetrical screen, the reported detection rate increases to between 43.8% and 85.5%.^{7,12,13} In contrast, if fetal echocardiography, defined as a detailed, focused assessment of the fetal cardiovascular system, is performed, then rates of detection are significantly higher, and diagnostic accuracy rates may exceed 85% to 90%.^{12,14} Given the disparity in rates of detection between those specialising in fetal echocardiography and routine obstetrical screening, the question of who should be referred for fetal echocardiography remains an important consideration.

Currently, the American Society of Echocardiography recommends fetal echocardiography for fetal, maternal, and familial indications (Table 10-1).¹⁵ In the past, many women were referred for fetal echocardiography due to a family history of congenital cardiac disease, an umbilical cord containing two vessels, maternal diabetes, or maternal exposure to teratogens. Patterns of referral, however, have changed on account of improved techniques becoming

available for imaging. Referrals for fetal echocardiography producing a high yield now include an abnormal obstetrical ultrasound evaluation, in which up to two-thirds of referrals have congenital cardiac malformations, and a chromosomal anomaly, with half of such referrals proving to have congenital cardiac lesions.^{16,17} Referrals with a low yield include presence of a single umbilical artery, or exposure to teratogens, with congenital cardiac lesions detected infrequently in mothers referred with these indications.^{16,17} A family history of congenital cardiac disease accounts for between one-quarter and one-third of all referrals for fetal echocardiography, but less than one-twentieth of cases with detected malformations.^{16,17} Increased nuchal translucency noted on screening during the first trimester, from 10 to 13 weeks of gestation, has now emerged as an important indication for fetal echocardiography. Indeed, increased nuchal translucency of greater than 3 mm as seen during scanning when the fetus is aged from 10 to 14 weeks is a published marker for aneuploidy.¹⁸⁻²³ Even in the absence of a chromosomal anomaly, fetuses found to have increased nuchal translucency on early scanning have been shown to be at increased risk for congenital cardiac disease.^{24,25} Fetuses conceived via artificial fertilisation, particularly when using intracytoplasmic injection of sperm, have a twofold increased risk of major birth

TABLE 10-1

INDICATIONS FOR FETAL ECHOCARDIOGRAPHY

Maternal Indications

- Family history of congenital cardiac disease
- Metabolic disorders, such as phenylketonuria or diabetes
- Exposure to teratogens
- Exposure to inhibitors of prostaglandin synthetase, such as ibuprofen, salicylic acid, or indomethacin
- Infection with rubella
- Autoimmune disease, such as systemic lupus erythematosus, or Sjögren's syndrome
- Familial inherited disorders, such as Ellis van Creveld syndrome, Marfan's syndrome, or Noonan's syndrome
- Artificial fertilisation

Fetal Indications

- Abnormal result following obstetrical ultrasonic screening
- Extracardiac abnormality
- Chromosomal abnormality
- Arrhythmia
- Hydrops
- Increased nuchal translucency in first trimester
- Multiple gestation and twin-twin transfusion

defects, including congenital cardiac disease, compared to infants conceived naturally.²⁶ While somewhat controversial, it is increasingly recognised that the frequency of congenital anomalies is increased in this population, and fetal echocardiography is therefore of benefit to these families.

TIMING OF FETAL ECHOCARDIOGRAPHY

Fetal echocardiography is best performed between 18 and 22 weeks of gestation. At this gestational age, there is adequate amniotic fluid to allow good visualisation of the cardiac structures and vasculature. After 30 weeks gestation, the increase in the fetal body mass, and the shadowing effects of the fetal ribs, may make acquisition of images more difficult. Maternal transabdominal fetal imaging may be performed between 15 and 18 weeks gestation, although visualisation may be suboptimal. New interest has emerged in early maternal transabdominal or trans-vaginal scanning at 11 to 14 weeks of gestation, especially in populations known to be at high risk, such as those noted to have increased nuchal translucency during scanning at 10 to 14 weeks, those with suspected aneuploidy, or those with a family history of congenital cardiac disease. Feasibility studies have demonstrated adequate acquisition of images at these gestational ages for both maternal transabdominal and trans-vaginal imaging. Diagnostic transabdominal images have been reported in 98.7% of cases, with abnormalities detected in 13 of 226 fetuses studied.²⁷ In this study, only 4 of 213 minor structural abnormalities were missed on the initial scan.²⁷ Others have shown that the four-chamber view can be obtained using trans-vaginal imaging in all cases, with extended views of the heart obtained in almost all of these instances.²⁸ In this study, three cases of major congenital cardiac disease were diagnosed on the initial trans-vaginal scan, while three cases were diagnosed later in gestation.²⁸

MODALITIES FOR IMAGING

Cross sectional imaging remains the gold standard for the diagnosis of structural cardiac disease during fetal life. The Pediatric Council of the American Society of Echocardiography recommends obtaining multiple cross sectional tomographic views of the heart in order to make an accurate diagnosis.¹⁵ Fetal echocardiography should include an apical four-chamber view of the heart, an apical five-chamber view, a long-axis view of the left ventricular outflow tract, a long-axis view of the right ventricular outflow tract, a short-axis view at the level of the arterial trunks, a short-axis view at the level of the ventricles, a long-axis view of the caval veins, a view of the ductal arch, and a view of the aortic arch¹⁵ (Table 10-2 and Figs. 10-1 and 10-2). The fetal heart rate should be documented, and any arrhythmia confirmed with M-mode imaging. The diameters of the orifices of all valves should be measured in systole at right angles to the plane of flow.¹⁵ Reference ranges for the diameters of all valves over the course of gestation have been published.²⁹ Cardiac dysfunction may be assessed by cross sectional interrogation by the presence of ascites, pleural or pericardial effusions, skin oedema, and cardiomegaly, as defined by a ratio of cardiothoracic areas of greater than 0.36.³⁰ A ratio of cardiothoracic areas greater than 0.6 is associated with an extremely poor outcome.³¹

TABLE 10-2

ESSENTIAL COMPONENTS OF THE FETAL ECHOCARDIOGRAM

Feature	Essential Component
Anatomical overview	Fetal number and position in the uterus Establish stomach position and arrangement of abdominal organs Establish cardiac position
Biometric examination	Cardiothoracic ratio Biparietal diameter Femoral length
Cardiac imaging views/sweeps	Four-chamber view Four-chamber view angled towards great arteries (five-chamber view) Long-axis view (left ventricular outflow) Long-axis view (right ventricular outflow) Short-axis sweep, cephalad angling to include the three-vessel view Long-axis view of caval veins Ductal arch view Aortic arch view
Doppler examination	Inferior and superior caval veins Pulmonary veins Hepatic veins Venous duct Oval foramen Atrioventricular valves Arterial valves Arterial duct Transverse aortic arch Umbilical artery Umbilical vein
Measurements	Atrioventricular valvar diameter Arterial valvar diameter Pulmonary trunk Ascending aorta Right and left pulmonary arteries Transverse aortic arch Ventricular length Ventricular short-axis dimensions
Examination of rhythm and rate	M-mode of atrial and ventricular mural motion Doppler examination of patterns of atrial and ventricular flow

Colour Doppler interrogation adds to the assessment of fetal cardiovascular wellbeing by establishing the degree of valvar stenosis and regurgitation, if present. Mild tricuspid regurgitation may be seen throughout gestation, and is frequently a benign finding,^{32,33} but tricuspid regurgitation detected during early scanning, from 11 to 14 weeks, may be a marker for aneuploidy, even in the absence of structural heart disease.³⁴ In contrast, regurgitation across the mitral, pulmonary, or aortic valves is usually not a normal finding and suggests pathology, secondary to underlying structural cardiac disease or fetal cardiac failure. Cardiovascular physiology can also be assessed by colour Doppler echocardiography by determining the direction of blood flow. In the normal fetal circulation, the direction of shunting is right to left at both the patent oval foramen and the arterial duct. Abnormal directions of flow at these sites may

Figure 10-1 Illustration of the tomographic planes used to image the fetal cardiovascular system. Imaging planes displayed are in a normal human fetus. Starting at the top left, the following views are demonstrated in a clockwise manner: 1, apical (four-chamber) view; 2, apical (five-chamber) view angled towards the aorta; 3, long-axis view of the left ventricular outflow tract; 4, long-axis view of the right ventricular outflow tract; 5, short-axis view at the level of the great vessels; 6, short-axis view with caudad angling at the level of the ventricles; 7, caval long-axis view; 8, ductal arch view; 9, aortic arch view. (With permission from the American Society of Echocardiography Guidelines and Standards for Performance of the Fetal Echocardiogram. *J Am Soc Echocardiogr* 2004;17:803–810.)

suggest cardiac disease. For example, left-to-right flow at the patent oval foramen, or bidirectional shunting through the arterial duct with reversal of flow in the transverse arch, may indicate inadequacy of the left ventricle.^{35,36}

Doppler echocardiography is a powerful tool with which to assess cardiovascular physiology and function, and is an important part of the comprehensive evaluation of the fetal cardiovascular system. Pathological conditions associated with elevated central venous pressures may manifest as changes in the Doppler flow patterns in the inferior caval vein, the venous duct, and the umbilical vein. After 18 weeks gestation, flow in the venous duct should be all antegrade with atrial contraction. As central venous pressure increases, there is first decreased flow, and ultimately reversal of flow seen with atrial contraction in the venous duct (Fig. 10-3). In the umbilical vein, there is normally continuous forward flow at low velocity. As central venous pressure increases, notching is seen at the end of diastole

in the umbilical venous flow. In severe cardiovascular compromise, there is absence of flow at end-diastole, with venous pulsations seen in the umbilical vein.

Doppler evaluation of the arterial system provides important information regarding fetal cardiovascular well-being. Doppler evaluation of the umbilical artery provides information concerning the health and state of the placental circulation (Fig. 10-4). The healthy placenta has a very low vascular resistance, and hence Doppler spectral display will demonstrate substantial antegrade flow during the diastolic phase of the cardiac cycle. Abnormally elevated placental vascular resistance, as seen in cases of intra-uterine retardation of growth, or in the donor fetus of a twin-twin transfusion syndrome, can be identified by the presence of diminished, or even reversed, flow in diastole (Fig. 10-5).

Changes in cerebrovascular resistance may be seen in conditions of altered cardiac output, and with different forms of congenital cardiac disease. These changes are a

Figure 10-2 Illustrations of the anatomical correlates for each of the designated tomographic imaging planes used for imaging of the fetal cardiovascular system. Each numbered view relates to the clockwise illustration of the fetal heart in Figure 10-1. Figure 10-3 A, Doppler spectral display of the normal pattern of flow in the venous duct. Note that flow is phasic, but all antegrade below the baseline. B, An abnormal pattern of flow in the venous duct. Arrows point to reversal of flow (above the baseline) with atrial contraction. Such patterns are seen in the presence of an abnormal compliance of the right ventricle.

Figure 10-4 Colour Doppler image of the normal umbilical cord. Two arteries (blue) and one umbilical vein (red) are seen.

Figure 10-5 Doppler spectral display of blood flow in the umbilical cord. Umbilical artery flow is above the baseline and umbilical venous flow is below the baseline. In the top panel, the arrows point to reversal of flow in the umbilical artery suggesting markedly elevated placental vascular resistance. The bottom panel is obtained from a normal umbilical cord with abundant diastolic flow in the umbilical artery indicating normal placental vascular resistance.

manifestation of auto-regulatory mechanisms of the fetal cardiovascular system, in which there is a natural tendency to preserve flow of blood to vital organs such as the brain. When flow to the brain is diminished due to an overall decrease in cardiac output as a consequence of myocardial dysfunction, or due to an anatomical impediment, vascular resistance will be lower than normal in the middle cerebral artery as the brain attempts to augment volume and flow (Fig. 10-6). Hence, in the presence of left-sided obstructive lesions, the resistance measured in the middle cerebral artery decreases. In the setting of right-sided obstructive lesions, in contrast, the resistance increases.^{37,38} In addition, in fetuses with cardiovascular compromise, there may be a redistribution of the cardiac output away from the placenta and toward the brain, the so called brain sparing effect.^{39–41} Typically, the ratio of resistance in the middle cerebral artery compared to the umbilical artery is greater than 1. With hypoxia or inadequate cardiac output, there may be cephalisation of flow, characterised by a ratio of resistance in the middle cerebral artery compared to the umbilical artery of less than 1. Assessment of patterns of antegrade flow across the atrioventricular valves also provides important information regarding diastolic function and ventricular compliance (Fig. 10-7). Compared to mature myocardium, the fetal myocardium is comprised of greater non-contractile elements.⁴² As a result, the fetal heart exhibits impaired myocardial relaxation, reflected by a lower velocity of the Doppler E wave compared to that of the A wave. Over the course of gestation, the ratio of the velocities of the E to A waves increases progressively. In severe cases of diastolic dysfunction, such as in the recipient twin with twin-twin transfusion syndrome, or in ventricles compromised by endocardial fibroelastosis, the E and A waves may merge into a single peak (Fig. 10-8).

Novel imaging techniques, such as three-dimensional echocardiographic interrogation, or use of magnetic resonance imaging, remain relatively untested in the detailed assessment of the fetal cardiovascular system, but may be of increasing importance in the future. Feasibility studies assessing the usefulness of such techniques in providing detailed information above and beyond screening are currently underway.^{43–49}

CONGENITAL CARDIAC LESIONS AT RISK FOR PROGRESSION DURING FETAL LIFE

With the growing application of fetal echocardiography, it has become apparent that some malformations undergo developmental change during the second and third

Figure 10-6 A, Doppler spectral display of normal flow in the middle cerebral artery flow. The arrows point to diastolic flow at low velocity suggesting elevated, normal cerebrovascular resistance. B, Abnormal flow. The arrows point to relatively elevated velocity of diastolic flow, suggesting diminished cerebrovascular resistance, an abnormal finding in a fetus with poor myocardial function and low cardiac output.

Figure 10-7 Four-chamber view with Doppler interrogation sample positioned beneath the tricuspid valve at the right ventricular inflow. LV, left ventricle; RV right ventricle.

Figure 10-8 Doppler spectral display of flow across the tricuspid valve. The arrows in the top panel point to the normal double-peaked pattern. In the bottom panel, the arrow points to a fused single peak of inflow, suggesting abnormal right ventricular compliance.

trimesters of gestation. Serial evaluation from the point of initial identification is, therefore, an important part of care for these families. At present, there is a paucity of knowledge concerning the overall potential for progression of disease and the natural history of congenital cardiac disease in the fetus. In some diseases, nonetheless, progression during fetal life is known to be important.

Left-sided Obstructive Lesions

Critical aortic stenosis is readily recognisable in the early second trimester by the appearance of a dilated and dysfunctional left ventricle, lined with endocardial fibroelastosis, and a thickened and stenotic aortic valve. In fetuses recognised to have left-sided obstructive lesions, those with patency of the aortic valve who required functionally univentricular palliation at birth were shown to have either bidirectional, or left-to-right, flow across the patent oval foramen, and reversal of flow in the distal transverse arch.⁵⁰ At term, the left ventricle in many of these fetuses was found to be hypoplastic, despite findings of normal left ventricular length earlier in gestation.⁵⁰ Others have published predictors for progression of critical aortic stenosis to hypoplasia of the left heart, with left-to-right flow across the patent oval foramen, reversal of flow in the distal transverse arch, a monophasic pattern of flow across the mitral valve as shown by Doppler interrogation, and significant left ventricular dysfunction all predicting progression during fetal life from critical aortic stenosis to hypoplastic left heart syndrome.³⁶ In the hopes of achieving a postnatal biventricular repair for these fetuses initially having critical aortic stenosis, much interest has focused on developing techniques for fetal intervention. Different institutions have reported technical success for these fetal interventions,⁵¹⁻⁵⁸ although the proportion of fetuses progressing to postnatal biventricular repair remains disappointingly low.

Right-sided Obstructive Lesions

Similar to obstruction within the left-sided outflow tract, right-sided obstruction may also progress over the course of gestation. In the setting of tetralogy of Fallot or valvar pulmonary stenosis, obstruction may progress from mild

to severe stenosis, or even atresia.^{59–61} To prevent the development of right ventricular hypoplasia in such fetuses with critical pulmonic stenosis or atresia and impending hydrops, some have successfully dilated the pulmonary valve during fetal life, and achieved a biventricular repair postnatally.^{62,63} Specific criteria for predicting the development of critical obstruction, nonetheless, remain elusive, and await a more complete understanding of the natural history of these lesions.

Regurgitant Lesions

In Ebstein's malformation, severe regurgitation across the malformed tricuspid valve may lead to decreased forward flow through the pulmonary valve, with the development of severe pulmonary stenosis, or even atresia, over the course of gestation.^{64,65} These fetuses are at significant risk for the development of hydrops and death during gestation. If the fetus does survive to term, the combination of severe tricuspid regurgitation, pulmonary atresia, and pulmonary hypoplasia is associated with a particularly poor outcome, with few postnatal survivors.^{64,65}

Progressive Restriction at the Patent Oval Foramen

In those with transposition, or hypoplastic left heart syndrome, the patent oval foramen may become progressively restrictive, or may even close over the course of gestation.^{66–68} Closure of this interatrial communication may result in particularly poor outcomes, with the development of arrhythmias, hydrops, or fetal cardiac dysfunction.⁶⁷ Fetuses with a restrictive foramen or an intact atrial septum in the setting of transposition are at risk for profound postnatal cyanosis, and should be delivered in a centre capable of performing immediate balloon atrial septostomy after birth. Fetuses with a restrictive or intact interatrial communication in the setting of hypoplastic left heart syndrome are at risk for left atrial hypertension, with the development of lethal pulmonary vasculopathy.^{69,70} Current rates of survival for neonates with hypoplasia of the left heart and an intact atrial communication remain disappointingly low, ranging from 47% to 57%.^{71,72} Strategies employed to improve the neonatal rates of survival include early catheter-based interventions,^{71,72} surgical atrial septotomy, or immediate cannulation for extracorporeal oxygenation after birth. At our own institution, we currently favour delivery by caesarian section in a cardiac operating room, with cardiothoracic anaesthesia available, and immediate postnatal intervention on the atrial septum either via a catheter-based or surgical approach. The initial stage of palliation is delayed for a few days to allow stabilisation. In an attempt to avoid all postnatal instability, some centres have advocated ultrasonically guided fetal atrial septoplasty⁷³ or laser atrial septotomy,⁷⁴ for those fetuses with hypoplasia of the left heart and a highly restrictive or intact atrial communication. Selection of candidates for fetal atrial septoplasty remains an important consideration. Direct measurement of the patent oval foramen may be unreliable during fetal life in predicting the postnatal size of the interatrial communication.⁷⁵ Multiple investigators, nonetheless, have demonstrated the value of assessing the forward and reverse patterns of flow in the pulmonary veins by Doppler

interrogation to predict the need for immediate postnatal intervention.^{75–78}

POSTNATAL OUTCOMES

As critical care and cardiac surgery continue to improve, rates of neonatal survival for infants born with prenatally diagnosed congenital cardiac malformations have similarly improved. Whether prenatal diagnosis of the defects alone improves neonatal survival remains controversial. A number of studies have failed to demonstrate a difference in neonatal survival after surgical repair among infants diagnosed prenatally compared to those diagnosed postnatally,^{79–83} although some have reported improved survival in infants prenatally diagnosed with hypoplasia of the left heart, and transposition, respectively.^{84,85} Prenatal diagnosis, nonetheless, does impact on morbidity. Numerous studies have demonstrated improved preoperative conditions in infants prenatally diagnosed with ductal-dependent lesions, with the potential for better long-term neurodevelopmental outcomes.^{79,80,82,86} Multi-institutional studies are needed to assess the effect of prenatal diagnosis upon long-term neurodevelopmental outcome.

This study investigates the pulmonary venous Doppler flow patterns in fetuses with hypoplastic left heart syndrome and a restrictive interatrial communication. In this study, a ratio of the forward to reverse flow in the pulmonary veins less than 5 was predictive of the need for emergent atrial septectomy in the newborn period.
- Mahle WT, Clancy RR, McGaurn SP, et al: Impact of prenatal diagnosis on survival and early neurologic morbidity in neonates with the hypoplastic left heart syndrome. *Pediatrics* 2001;107:1277–1282.

This study explores whether prenatal diagnosis impacts upon survival and early neurologic morbidity in neonates with hypoplastic left heart syndrome. The authors concluded that mortality was not significantly different between the group diagnosed prenatally compared to postnatally. There were fewer adverse perioperative neurologic events in those patients with a prenatal diagnosis.

- Tworetzky W, McElhinney DB, Reddy VM, et al: Improved surgical outcome after fetal diagnosis of hypoplastic left heart syndrome. *Circulation* 2001;103:1269–1273.

In this study, the authors concluded that prenatal diagnosis of hypoplastic left heart syndrome was associated with improved clinical state prior to surgery, and with improved survival after the first stage of palliation in comparison with patients diagnosed after birth.

Prematurity and Cardiac Disease

PATRICK J. McNAMARA

On average, up to one-eighth of liveborn infants in the developed world are born prior to term. These rates have increased as a consequence of assisted reproductive technology, and earlier intervention for either maternal or fetal wellbeing. The causes of birth prior to term are many (Table 11-1). The care of the premature neonate has improved dramatically over the past 100 years, during which time mortality rate has fallen from 40 deaths for each 1000 live births at the turn of the 20th century, to the current rates of 4 deaths per 1000 live births in the developed world. These improvements are a direct result of enhanced maternal health, and access to quality obstetric and neonatal intensive care. Birth weight remains the major risk factor for neonatal mortality (Fig. 11-1). The past two decades have witnessed a number of significant advancements in neonatal care, most notably maternal administration of antenatal steroids,¹ the ability to replace surfactant,² use of inhaled nitric oxide,^{3,4} increased scientific evidence for routine practices, and superior equipment, such as ventilators and incubators. In addition, an increased number of neonatal conditions requiring intensive care are being recognised antenatally, which allows focused resuscitation, and timely intervention by specialist teams. This is particularly relevant for neonates with congenitally malformed hearts, particularly premature infants, who represent the most critical and potentially vulnerable patients. Despite regionalised perinatal health care, from one-tenth to one-third of those born with extremely low weight (Box 11-1) are delivered outside tertiary neonatal centers. Although overall survival for premature infants in general has improved, mortality remains high, particularly at the limits of viability (Table 11-2). The outcome for neonates born outside tertiary centres is less favourable when compared to those patients

delivered and resuscitated at perinatal centers specialised in coping with those at high risk.^{5,6} A large population-based study of mortality and disability, with the acronym EPICURE, was conducted in the United Kingdom of all infants born alive between the gestational ages of 22 and 25 weeks.^{7,8} Survival at 30 months reached just over 40% in neonates born at 25 weeks of gestation, falling to 10% for those born at 23 weeks of gestation. Moderate-to-severe disability occurred in almost half of the survivors when compared to school classmates at the age of 6 years. The contribution of cardiovascular performance and systemic haemodynamics to ongoing neonatal morbidity is poorly understood. Enhanced cardiovascular monitoring, and earlier therapeutic intervention, may prove to be a necessary step towards improving survival further, and minimising adverse neurodevelopmental sequels.

THE TRANSITIONING CIRCULATION

The condition of the infant at birth is dependent, in part, on intra-uterine wellbeing and growth. Intra-uterine growth retardation is the failure of the fetus or infant to achieve his or her predetermined genetic potential. Typically, the pre-term infant is below the third centile for weight, length, and head circumference. The consequences to the developing heart include cardiac hypertrophy, abnormal diastolic performance, and impaired vascular relaxation.⁹⁻¹¹ Doppler interrogation of fetal and neonatal mitral valve velocities revealed lower E wave amplitude compared with normal mature mitral E peaks.^{12,13} Impaired early left ventricular filling may relate to a diminished ability to relax, and higher muscular stiffness. The implications may include impaired myocardial performance, hypertension, and

TABLE 11-1

FACTORS CONTRIBUTING TO SPONTANEOUS PRETERM DELIVERY, OR THE NEED FOR EARLIER THERAPEUTIC INTERVENTION

Maternal	Placental	Fetal	Miscellaneous
Pre-eclampsia	Intra-uterine infection, or premature rupture of membranes	Chromosomal abnormality	Cervical incompetence
Systemic hypertension		Fetal distress	Idiopathic
Renal failure	Placental abruption	Hydrops fetalis	Familial
Diabetes mellitus	Antepartum haemorrhage	Congenital infection, such as toxoplasmosis, rubella, or cytomegalovirus	
Infection of the urinary tract	Uterine stretch		
Chronic disease	• Multiple pregnancies • Polyhydramnios • Uterine abnormality		

Figure 11-1 Causes of perinatal mortality (England and Wales, 1998).

BOX 11-1

Relevant Neonatal Definitions

Preterm: A neonate born prior to 37 weeks of completed gestation

Near-term: A neonate between the 34th and 37th weeks of gestation

Low birth weight: A neonate born weighing less than 2500 g

Very low birth weight: A neonate born weighing less than 1500 g

Extremely low birth weight: A neonate born weighing less than 1000 g

Perinatal mortality rate: The number of stillbirths and early neonatal deaths, those occurring within 6 days of birth, per 1000 live births and stillbirths

Neonatal mortality rate: The number of neonates dying in the first 4 weeks, specifically within 27 completed days of life, for each 1000 live births

Intra-uterine growth retardation: Growth parameters below the third centile for corrected gestational age. Asymmetric retardation is characterized by sparing of the head, the circumference of the head being greater than the third centile.

TABLE 11-2

NEONATAL MORTALITY ACCORDING TO BIRTH WEIGHT

Birth Weight (grams)	Births (%)	Neonatal Mortality per 1000 Live Births in Each Subgroup
Greater than 2500	92.4	0.9
Less than 2500	7.6	48
Less than 1000	1.4	214

hypotension. Poor glycaemic control during pregnancy, particularly in the setting of maternal diabetes, is a known risk factor for structural heart disease and hypertrophic cardiomyopathy.^{14–16} In severe cases, where there is placental malfunction leading to retardation of growth, the same vascular and myocardial dysfunction may occur as described above.

PHYSIOLOGY OF THE POSTNATAL TRANSITION

The preterm infant undergoes dramatic cardiorespiratory changes at birth, which coincide with improved lung compliance and termination of the placental circulation. These critical adaptive changes:

- Include increased pulmonary blood flow, to about 20 times fetal levels
- Occur in part due to the exposure of the pulmonary vascular bed to higher alveolar concentrations of oxygen than the relatively hypoxic intra-uterine environment. Other metabolically active substances, such as metabolites of prostaglandin, bradykinins, or histamine, may play some role through inducing pulmonary vasodilation.
- Include alteration in flow through fetal channels such as the arterial duct and oval foramen, which may last for many days. The major change in flow through fetal channels is either a direct result of increased flow to the lungs, or improved systemic arterial tensions of oxygen. Increased left atrial pressure secondary to improved pulmonary venous return causes displacement of the flap of the oval foramen over the rims of the fossa, thus abolishing any right-to-left atrial flow. The pattern of flow through the arterial duct is significantly altered as lung compliance improves and pulmonary vascular resistance decreases. An increase in systemic vascular resistance also occurs once the compliant placenta is removed from the systemic circuit, and as a result of systemic vasoresponsiveness to increased tensions of oxygen. This will also contribute to increased transductal flow. The architecture of the arterial duct prior to term differs such that ductal tone is less responsive to oxygen, thus delaying closure and potentially contributing to excessive flow to the lungs and compromised systemic flow. The administration of surfactant can alter transductal flow significantly through reduced pulmonary vascular resistance. There is evidence of functional closure by 6 hours in some immature patients, although this is rare.¹⁷
- Include improved left and right ventricular outputs to meet the metabolic needs of immature neonate with insufficient thermoregulatory mechanisms and increased work of breathing. The transition from right to left ventricular dominance occurs over hours, and is secondary to increased left atrial preload and left ventricular afterload. In total, there is a threefold increase in left ventricular output, which is necessary to meet the increased demands of the body. The enhanced ability of the left ventricle to increase its output is related, in part, to elimination of constraint by the pressure-loaded right ventricle.

REGULATION OF MYOCARDIAL PERFORMANCE

Architecture of the Myocyte

Fetal myocardial tissue consists of 70% noncontractile tissue, compared to 40% in the mature adult heart. Histological studies have shown that the myocytes making up the left ventricular myocardium are aligned circumferentially in the mid wall, and longitudinally in the subepicardial and subendocardial layers of the walls.^{18,19} Studies of isolated myocardial tissue in fetal and adult lambs suggest

that fetal myocardium is less compliant. Ventricular myocytes change considerably as they transition from fetal to post-natal life. The immature sarcomere and contractile apparatus is relatively disorganised. Myofibrils are irregular and scattered along the interior of the cell. Intra-uterine and early postnatal cardiac growth is a combination of both hyperplasia and hypertrophy. Exposure of the developing rodent heart to dexamethasone led to cardiac hypertrophy, characterised by myocytes which were longer and wider, with increased volume.²⁰ Biventricular hypertrophy is a recognised complication of exposure of the preterm myocardium to prolonged and high doses of steroids.²¹ Neonates born to mothers who had received a single antenatal course of steroids had higher systolic blood pressures, and increased myocardial thickness, suggesting modified myocardial development.²² The nature of these changes may relate to earlier transition from a phase of hyperplasia to hypertrophy. The functional consequence of an enlarged hypertrophic myocardium, with a reduced overall number of myocytes, is unknown.

Activation of the Myocyte

In contrast to adults, immature myocytes lack transverse tubules, are smaller in size, and have a greater ratio of surface area to volume.²³ They are more reliant on transsarcolemmal fluxes of calcium for contraction and relaxation.²⁴ The high ratio of surface area to volume, and the subsarcolemmal location of myofibrils, supports direct calcium delivery to and from the contractile proteins. The sodium-calcium exchanger is the major conduit for attachment of calcium to, and release from, the contractile elements.²⁵

Control of Myocytic Activation

The control mechanisms governing contraction and relaxation in the immature heart are poorly understood, but thought to be substantially different from the fully mature heart. In the mature heart, graded control of release of calcium is related to so-called L-type activity, which triggers release from the sarcoplasmic reticulum. Graded control of release in immature myocytes is thought to be related to factors influencing the activity of the sodium-calcium channel. Recently isoproterenol-induced β -adrenergic stimulation of sodium-calcium exchanger was identified in guinea-pig ventricular myocytes. An improved understanding of factors which govern myocardial contractility and relaxation may facilitate more physiologically appropriate choice of therapeutic interventions in premature infants.

Performance and Physiology of the Immature Myocardium

At physiological heart rates, the immature myocardium shows a positive relationship, albeit that contractility falls with extreme tachycardia. Both the force-rate trajectory, and the optimal heart rate, reflects myocytic function and global myocardial contractile behaviour. Developmentally, the immature myocardium has been shown to exhibit a higher basal contractile state, and a greater sensitivity to changes in afterload.^{26,27} The intolerance of the immature myocardium to increased afterload may be attributable to differences in myofibrillar architecture, or

immaturity of receptor development or regulation.²⁸ The Frank-Starling law appears less applicable to the immature myocardium.²⁹

HAEMODYNAMIC ASSESSMENT AND MONITORING

The consequences of haemodynamic instability include necrotising enterocolitis, intraventricular haemorrhage, and periventricular leucomalacia, all of which may lead to mortality or adverse neurodevelopmental outcomes. Intraventricular haemorrhage occurs in up to three-tenths of infants born with very low weight, most commonly in the first 7 hours of life. The origin of the haemorrhage is the germinal matrix, an immature network of capillaries highly susceptible to hypoxaemia, hypercapnaemia, and altered cerebral blood flow. Periventricular leucomalacia is a loss of white matter in the watershed areas around the lateral cerebral ventricles secondary to hypoxic-ischaemic injury. The infant born at very low weight is highly susceptible to such morbidities, necessitating focused cardiovascular monitoring and targeted intervention in a timely fashion.

Is Blood Pressure a Reliable Measure of Circulatory Stability?

The determination of haemodynamic stability in premature infants is fraught with uncertainty, myths, and dogma without scientific validity. Suboptimal systemic blood flow is usually suspected on the basis of tachycardia, delayed capillary refill time, hypothermia, oliguria, altered blood pressure, metabolic acidosis, and increased levels of lactate in the plasma. Blood pressure readings are readily available at the bedside as a continuous stream of data from indwelling arterial lines, or periodically using a validated oscillometric cuff method.³⁰ The approach to monitoring and guiding therapeutic intervention has relied on using mean arterial pressure as a surrogate of the adequacy of tissue perfusion and oxygenation. This reasoning is based on an assumed proportionality between blood pressure and systemic blood flow.³¹ In 1992, a report from the former British Paediatric Association stressed the importance of monitoring blood pressure in order to guide early therapeutic intervention, and thus prevent adverse neurological sequelae.³² It was suggested that mean arterial pressure equivalent to the gestational age in weeks is adequate as a minimum value. The group also suggested the need to establish accurate normative ranges for systolic and diastolic blood pressure. Unfortunately, achieving a mean blood pressure equal to gestational age has now become dogma, and the standard on which therapy is based. Normative centiles for systolic blood pressure that take into account both gestational age at birth and postnatal age have been developed, but are rarely used.³³ Monitoring blood pressure in isolation is problematic for a number of reasons. First, blood pressure is but one surrogate of circulatory stability. Second, the concept of numerical hypotension as mean blood pressure less than gestational age in weeks has not been validated against indexes of perfusion of end-organs. Third, important changes in either systolic or diastolic blood pressure may be missed. The systolic pressure indicates the pressure generated by the left ventricle, whereas the diastolic pressure reflects local perfusion of the

Figure 11-2 Relationship between mean arterial pressure and left ventricular output or superior vena cava flow in 46 neonates assessed at three time points following surgical ligation of the ductus arteriosus. The dashed lines represent lower acceptable limits according to gestational norms (From Teixeira LS et al: *Pediatr Res* 2006;59:239.).

tissues. In neonates with a haemodynamically significant arterial duct, diastolic pressure is oftentimes compromised in isolation of changes in mean arterial pressure. This may have an unappreciated adverse effect on coronary arterial perfusion, and subsequently on myocardial performance. The relationship between mean blood pressure and cardiac output is also weak (Fig. 11-2). The finding of neonates with numerical hypotension, but no clinical or biochemical signs of systemic flow, and conversely patients with normal or high blood pressure but signs of circulatory compromise, is not uncommon. It must be recognised that blood pressure is but a surrogate of perfusion, and not the end-point of interest.

Does Hypotension Lead to Brain Injury?

The rationale for treating hypotension is based on two important considerations. First, the cerebral circulation becomes pressure-passive below a critical level for blood pressure (Fig. 11-3).^{34,35} The auto-regulatory mechanism is thought to fail below a mean arterial pressure of 30 mm Hg.³⁶ There is also evidence suggesting that neonates with hypotension have impaired cerebral oxygenation as determined by near-infrared spectroscopy, and are at increased risk of intracranial haemorrhage or periventricular leucomalacia.³⁷ Other investigators have shown no relationship between blood pressure and cerebral blood flow.³⁸ Second, associations have been shown between adverse neurological consequences and systemic hypotension.³⁹⁻⁴² There is a significant body of evidence, nonetheless, which challenges these assumptions. For example, there is data suggesting that the association of hypotension to injury to the white matter and adverse neurodevelopmental outcome is not one of cause and effect, but an epiphenomenon. Studies with superior designs, and larger numbers, have failed to demonstrate any positive association between blood pressure and adverse neurological outcomes.⁴³⁻⁵² When corrected for associated risk factors, such as intra-uterine growth retardation, postnatal use of steroids, and chronic lung disease, the association between hypotension and abnormal neurodevelopmental outcomes was lost.⁵³ The discrepancy between individual studies may reflect the fact that the association is much more complex than any direct effect of blood pressure on cerebral blood flow (Fig. 11-4). There may be concurrent changes in cardiac output and regional differences

Figure 11-3 Schematic drawing of the relationship between cerebral blood flow and mean arterial pressure. The flat portion of the curve reflects the auto-regulatory plateau. Below the lower part of the plateau cerebral blood flow falls proportionate to mean arterial pressure. (From Greisen G: Autoregulation of cerebral blood flow in newborn babies. *Early Hum Dev* 2005;81:423-428.)

in flow of blood independent of blood pressure that are influencing cerebral perfusion, but these studies have not been performed.

How Should We Monitor the Preterm Circulation?

Failure of the neonatal transition may lead to myocardial dysfunction, low cardiac output, and hypotension, which may compromise perfusion of the end-organs with consequent damage. The vulnerability of the cerebral circulation in the first 72 hours of life increases the likelihood of injury to the brain more than any other organ. It is essential that the systemic flow be monitored adequately at all stages. Tachycardia and capillary refill time are poorly validated and non-specific measures of systemic flow. In isolation, capillary refill time is inaccurate, highly subjective, and a poor overall predictor of the adequacy of perfusion.⁵⁴ The measurement of cardiac output at the bedside is a useful adjunct to the clinical assessment and there is normative data for both right and left ventricular outputs.^{55,56} The normal range for cardiac output in normal premature infants is between 170 and 320 mL/kg/min. Unfortunately these measurements are potentially inaccurate in the early neonatal period due to the effects of transductal shunting. Recently, measurement of flow in the superior caval vein has been proposed as a novel method of assessing the adequacy of systemic flow, as it is not confounded by atrial or ductal shunts.⁵⁷ As four-fifths of flow in the superior caval vein represents venous return from the head and neck, such measurements may provide novel insights into any association between regional cerebral blood flow and cerebral injury. Reduced flow in the superior caval vein is common in premature infants in the first 24 hours, reaching a nadir between 8 and 12 hours which coincides with increased systemic vascular resistance. Neonates with the lowest flow are at greatest risk of intraventricular haemorrhage (Fig. 11-5).⁵⁸ When 3-year neurodevelopmental assessment was performed, low superior caval venous flow remained significantly associated on multiple logistic regression analysis, when adjusted for gestation and birth weight, with an abnormal developmental quotient and the combined endpoint of death and abnormal developmental

quotient.⁵⁹ Both blood pressure and systemic flow are important determinants of the likelihood of altered perfusion, and neither should be monitored nor treated in isolation, without consideration of the influence of the other.

CARDIOVASCULAR PROBLEMS UNIQUE TO THE PRETERM INFANT

The Haemodynamically Significant Arterial Duct

Patency of the arterial duct is a common problem in preterm babies, especially those born with extremely low weight. Although functionally essential for the normal fetal circulation, persistent ductal patency may have significant effects in preterm infants that include pulmonary overcirculation and systemic hypoperfusion. Persistent patency is found in about half of babies born at less than 29 weeks gestation, and/or weighing under 800 g.^{60,61}

Biology of Normal Closure

Ductal closure is not immediate, particularly in infants born with extremely low weights, and occurs in two stages. Functional closure depends on the vasoconstricting action of humoral and biochemical factors on the muscular layer of the duct. This constriction results in the development of a zone of profound hypoxia in the media, which is the sentinel stimulus for irreversible closure. Anatomical closure depends on the architectural remodeling of the ductal wall.⁶² It consists of extensive neointimal thickening, and loss of smooth muscle cells from the inner media.⁶³ The remodeling effects start at the pulmonary end, progressing toward the aortic insertion.⁶⁴ Both vasodilator prostaglandins, especially PGE_2 , and nitric oxide, oppose ductal closure during fetal life.^{65,66} In the second trimester, intimal cushions are formed that closely resemble the pathological intimal thickening seen in atherosclerotic disease.⁶⁷ The media is supplied with oxygen from either the lumen or its mural vessels. The thickness of the avascular zone, adjacent to the lumen, plays a critical role in determining the degree of hypoxia and subsequent remodeling of the ductal wall. Constriction of the circumferential and longitudinal muscle in the ductal wall leads to compaction, increased avascular thickness, and limits luminal supply of oxygen to both the avascular zone and the medial muscle.⁶³ The resultant hypoxia induces expression of vascular endothelial growth factor or cell death, depending on its severity. The geographic distribution of expression corresponds with the distribution and intensity of mural hypoxia.⁶⁸ The biologic consequences of these changes include a decline in tissue distensibility and increased contractile potential.⁶⁹ The ductal wall of fetuses during late gestation has a high level of intrinsic tone, which is further increased after delivery by unopposed oxygen-induced contractile forces.⁶⁸ After delivery, the increase in arterial content of oxygen, along with the decrease in circulating prostaglandins following placental separation,⁷⁰ and reduced intraluminal blood pressure, contribute towards ductal closure.^{71,72} As transductal flow decreases, the wall becomes progressively more ischaemic, and eventually fibrotic.⁷³

Ductal Closure in Infants Born with Extremely Low Weight

The duct remains patent in up to four-fifths of infants born prior to term and weighing below 1200 g. Such infants have no mural vessels in the medial layer, and are nourished entirely via transluminal diffusion or from adventitial

Figure 11-5 Box plot of the lowest superior caval vein (SVC) flow in the first 24 hours for neonates who developed severe intraventricular haemorrhage ($N = 18$) versus those who did not develop an intraventricular haemorrhage ($N = 99$). IVH, intraventricular haemorrhage. (From Kluckow M, Evans N: Low superior caval vein flow and intraventricular haemorrhage in preterm infants. *Arch Dis Child Fetal Neonatal Ed* 2000;82:188–94.)

vessels. The immature duct, when studied experimentally, has also been shown to have less intrinsic tone,⁶⁸ and lacks both intimal folds and circumferential medial musculature.⁷⁴ It is less responsive to oxygen,^{68,75} and more sensitive to prostaglandin E₂ and nitric oxide.⁶⁶ It is possible for the immature infant to develop comparable hypoxia in the medial muscle, but only if transluminal flow is completely obliterated. Even when the duct constricts, profound hypoxia in the medial wall and anatomical remodeling fail to develop.⁶³ A progressive increase in levels of nitric oxide synthetase in the ductal mural vessels after the first 15 days of life makes the preterm duct even less sensitive to prostaglandins.^{73,76} Non-steroidal anti-inflammatory agents, therefore, are less likely to be effective. In baboons, co-administration of an inhibitor of nitric oxide synthase, along with indomethacin, leads to increased contractility and luminal obliteration of the preterm duct.⁷⁷ There is data also to suggest that, in more mature preterms, those born prior to 33 weeks gestation, the arterial duct is also less sensitive to non-steroidal anti-inflammatory agents, although the mechanism has not been elucidated.⁷⁸

The Pathophysiological Effects of a Haemodynamically Significant Arterial Duct

Failure of ductal closure, coinciding with the normal postpartum fall in pulmonary vascular resistance, results in a left-to-right transductal shunt. The consequences may include pulmonary over-circulation and/or systemic hypoperfusion, both of which may be associated with significant morbidity (Fig. 11-6). The clinical impact is dependent on the magnitude of the shunt, and the ability of the infant to initiate compensatory mechanisms. These infants are less capable of compensating, and are prone to developing left ventricular failure, which may lead to alveolar oedema and/or low cardiac output syndrome.⁷⁹ The increased pulmonary flow, and accumulation of interstitial fluid secondary to the large ductal shunt, contributes to decreased lung compliance.⁸⁰ The cumulative effects of increasing or prolonged ventilator requirements and myocardial dysfunction may increase the risk of chronic lung disease.^{81,82} Systemic flow may also be compromised with ductal shunts due to retrograde diastolic flow in the aorta and the arteries supplying organs such as the kidneys and gut. The redistribution of systemic flow is significantly altered even with shunts of small volume. Oftentimes there may be significant hypoperfusion to the kidneys and gastrointestinal tract before a haemodynamically significant duct is clinically suspected.

This may lead to significant morbidity, including renal insufficiency, necrotising enterocolitis, intraventricular haemorrhage, and myocardial ischemia.^{83,84} Early detection and targeted intervention may potentially improve long-term neonatal outcomes.

Diagnosis of a Haemodynamically Significant Arterial Duct

Clinical Presentation

The classical clinical features include a systodiastolic murmur, hyperactive praecordium, bounding pulses, and wide pulse pressure. More commonly, a systolic murmur is audible that radiates widely across the praecordium and back. In many of those born prior to term, however, cardiac auscultation is unremarkable.⁸⁵ In the first week of life, despite the presence of a large duct, typical clinical signs are often absent. Such a situation is widely recognised as the silent duct. Surfactant, by assisting the natural post-natal fall in pulmonary arterial pressure, has been shown to alter the timing of clinical presentation, specifically, by increasing the volume of the systemic-to-pulmonary shunt, which leads to an earlier clinical presentation.^{86,87} The existence of a haemodynamically significant but silent duct has been confirmed by cardiac catheterisation^{88,89} and detailed echocardiographic evaluation.⁹⁰ Such a situation should be suspected in a setting of delayed hypotension during the second and third days, failure of oxygenation, increasing requirements for ventilatory support, or metabolic acidosis. The infant is more likely to present with both systolic and diastolic hypotension due to the inability of the immature myocardium to compensate for shunting at high volume throughout the cardiac cycle.^{91,92}

Ancillary Tests

Although not very sensitive, chest radiography may show cardiomegaly and/or signs of pulmonary congestion, while the electrocardiogram may show signs of left atrial or ventricular enlargement.^{93,94} The latter may be more useful for the identification of subendocardial ischaemia secondary to low coronary arterial perfusing pressures in neonates with a large duct, although this association has not been formally evaluated.

Echocardiographic Confirmation of the Haemodynamically Significant Arterial Duct

It is now standard of care, in many centers, to perform routine ductal and functional assessment within the first 72 hours of life due to the unreliability of clinical assessment, the increased likelihood of the ductal sensitivity to closure assisted by indomethacin, and the magnitude of the potential morbidities if left untreated. The determination of ductal significance using echocardiography involves

Figure 11-6 Schematic of morbidity attributed to the haemodynamically significant ductus arteriosus (HSDA) as a consequence of pulmonary over-circulation and systemic hypoperfusion. IVH, intraventricular haemorrhage; LCOS, low cardiac output syndrome; NEC, necrotising enterocolitis; PVL, periventricular leucomalacia. (Modified from Teixeira LS, McNamara PJ: Enhanced intensive care for the neonatal ductus arteriosus. *Acta Paediatr* 2006;95:394–403.)

assessment of size, patterns of transductal flow, systemic and/or end-organ perfusion, and characterisation of the degree of volume loading of the heart.

- The size of the duct is obtained from a suprasternal short-axis view (Fig. 11-7A) although measuring its internal diameter can be difficult, even with clear images. In addition the transductal diameter is not consistent throughout, often becoming tapered at the pulmonary end. A transductal diameter less than 1.5 mm is associated with retrograde or absent postductal aortic diastolic flow.¹⁷ A diameter of more than 1.5 mm resulted in a positive likelihood ratio of 5.5, and a negative likelihood ratio of 0.22 for prediction of the need for therapeutic intervention. In a prospective study of 116 neonates, transductal diameter was the most accurate echocardiographic marker in predicting clinical and haemodynamic significance.⁹⁵
- The pattern of transductal flow, estimated using pulse wave Doppler interrogation from a suprasternal short-axis view, can also be used to characterise ductal significance. High-velocity, continuous left-to-right flow is predictive of imminent functional closure, whereas a low-velocity pulsatile left-to-right flow pattern is likely to be clinically significant (Fig. 11-7B).⁹⁶
- The effects on systemic and/or end-organ perfusion may also be examined. Large ductal shunts are associated with decreased superior caval venous flow.^{58,97} This is relevant as low flow, less than 40 mL/kg/min, a surrogate of systemic perfusion, has been shown to correlate with increased risk of late intraventricular haemorrhage.⁵⁸ Evidence of end-organ hypoperfusion may be also inferred from Doppler assessment of the patterns of flow in the mesenteric, cerebral or renal arteries. Specifically, reversal or absence of diastolic perfusion is pathognomonic of a haemodynamically significant duct.^{98,99}
- Cross sectional echocardiography has also been used to quantify the degree of volume overload. Specifically, estimates of left atrial or left ventricular size have been used as surrogates of pulmonary over-circulation and/or volume loading. Although the measurement is standardised, it is not very specific, and is prone to error dependent on the operator.⁵⁷ The presence of a large atrial septal defect permitting left-to-right shunting will lead to further augmentation of pulmonary flow, potentially overestimating the magnitude of the ductal shunt.

Management of the Haemodynamically Significant Duct

The aims of treatment are to reduce pulmonary over-circulation and improve systemic blood flow. The decision to treat is based on both clinical and echocardiographic

findings, although the optimal time and method of ductal closure remain uncertain. Treatment should be classified as supportive intensive care strategies and therapeutic interventions aimed at closing the duct.

Focused Intensive Care

Ventilation. Strategies should be considered in attempts to minimise pulmonary over-circulation in a fashion comparable to other cardiac defects. This can be achieved by accepting P_{CO_2} between 45 and 55 mm Hg, arterial pH of 7.25 to 7.35, and oxygen saturations between 88% and 93%. Improvements in oxygenation and lung compliance may also be achieved by increasing the positive end expiratory pressure to levels that maintain optimal recruitment, minimise atelectasis-induced lung injury, and lead to improvements in myocardial performance and cardiac output by reducing left ventricular afterload.^{100,101}

Cardiotropic Support. The optimal treatment for hypotension and/or systemic hypoperfusion is closure of the duct, and not cardiotropic support. Excessive α -adrenergic stimulation, by agents such as dopamine or epinephrine, should be avoided, as the increased systemic vascular resistance may lead to increased left-to-right shunting or may further compromise an already dysfunctional left ventricle. Dobutamine or newer inodilators currently under investigation, such as milrinone, may be preferred if there is associated left ventricular dysfunction.

Fluid Management and Diuretic Therapy. A recent meta-analysis suggested that restriction of water to meet the physiologic needs, whilst avoiding dehydration, may prevent the duct from becoming clinically and haemodynamically significant.¹⁰² This strategy should not be routinely recommended, as it may lead to reduced left ventricular stroke volume and cardiac output, further compromising systemic flow. Fluid restriction may be considered in patients who become oliguric and/or volume overloaded during treatment with indomethacin. The evidence for routine diuretic therapy to promote ductal closure is also limited.^{103,104} This may relate to excessive new production of prostaglandin E_2 by the kidneys in babies treated with furosemide.¹⁰⁵ A systematic review of the co-administration of furosemide in indomethacin-treated neonates concluded that evidence was insufficient to support its routine administration.¹⁰⁶ Diuretics should be restricted to the treatment of pulmonary oedema or left ventricular failure in neonates awaiting ductal ligation.

Feeding. Special consideration should be given to feeding, particularly if there is reversal or absence of perfusion in the superior mesenteric artery, or there are additional risk

Figure 11-7 A, Two-dimensional echocardiographic representation of a large patent ductus arteriosus from a parasternal short-axis view. B, Pulsed wave Doppler interrogation at the mid-ductal level reveals unrestrictive laminar transductal flow. Ao, aorta; MPA, main pulmonary artery; PDA, patent ductus arteriosus.

factors, such as intra-uterine retardation of growth. Specifically, a more cautious feeding regime, and lower thresholds for discontinuation of feeds, or consideration to screen for necrotising enterocolitis, should be considered. It may also be advisable to withhold feeds during treatment, due to the potential effects of ductal steal and non-steroidal anti-inflammatory agents such as indomethacin on intestinal perfusion.⁹⁹

Specific Treatment

Accepted strategies include both medical and surgical options. The decision to treat is normally made on the following basis:

- Echocardiographic confirmation of a duct with an internal diameter greater than 1.5 mm and unrestrictive left-to-right ductal shunting.
- Clinical signs of pulmonary over-circulation, myocardial dysfunction, or end-organ hypoperfusion.

Therapeutic closure is not recommended in a setting of suprasystemic pulmonary hypertension, or right heart failure where exclusive right-to-left shunting is a means to off-load a stressed right ventricle.

Non-steroidal Anti-inflammatory Drugs

As prostaglandins play a major role in preserving ductal patency, inhibitors of cyclooxygenase are conventionally used to assist its closure. Medical treatment should not be attempted, whenever possible, without prior echocardiographic evaluation and exclusion of duct-dependent cardiac lesions. Indomethacin is currently the treatment of choice for ductal closure in preterm babies, although the ideal dose, duration, and/or time to intervene remains somewhat controversial. Therapeutic options include prophylactic therapy or early targeted intervention.

Prophylactic Treatment

The merits of prophylactic treatment in the first 24 hours of life are highly questionable. Although the numbers of patent ducts are reduced, two-fifths of neonates are unnecessarily treated as the duct may have closed spontaneously.¹⁰⁷ In addition, ongoing ductal patency, in a transitional circulation with elevated pulmonary vascular resistance and poor right ventricular function, may be necessary for augmenting pulmonary perfusion. Severe hypoxaemia, responsive to inhaled nitric oxide, was recently reported in premature infants born prior to 28 weeks following prophylactic exposure to ibuprofen on the first day of life.¹⁰⁸ Prophylactic treatment in the first 24 hours of life, therefore, is not recommended, as the risks substantially outweigh the benefits as outlined previously.

Therapeutic Treatment

Early intervention, on the first to third days, is preferable to late intervention after 1 week, as the risks of necrotising enterocolitis, pulmonary morbidity and need for surgical ligation are significantly reduced.¹⁰⁹ The choice of dose and duration of treatment is controversial.¹¹⁰ A targeted early approach to intervention appears the most effective and safest option. Treatment with indomethacin fails in up to half the infants born with extremely low weight.⁶¹ This may reflect architectural differences and remodelling in the most immature patients, as described earlier, in addition to the severity of illness. Antenatal administration of indomethacin is also associated with postnatal hypo-responsiveness, and

increased need for surgical ligation.¹¹¹ Architectural remodelling of the ductal wall, secondary to increased expression of vascular endothelial growth factor, and altered regulation of ductal tone by nitric oxide, has been demonstrated in a fetal ovine model.⁶⁹

Complications of Medical Treatment

The decision to use indomethacin should be carefully balanced against the potential pitfalls of treatment. These include impaired renal function and compromised cerebral and/or mesenteric blood flow. Ibuprofen is a related agent that has been shown to have comparable efficacy in achieving ductal closure.^{112–114} A recent meta-analysis confirmed these findings, but also demonstrated an improved safety profile with ibuprofen.¹¹⁵ Specifically, those treated with ibuprofen had lower levels of creatinine, improved urinary output, and were less likely to have cerebral or mesenteric vasoconstrictive effects. There is, however, a potential greater risk of kernicterus, because ibuprofen interferes with binding of bilirubin to albumin in the serum when given in usual doses.¹¹⁶

Surgical Intervention

Surgical ligation is normally indicated after failure of medical therapy, or where medical therapy is contraindicated. The procedure is most commonly performed from a lateral subcostal approach, although video-assisted thoracoscopic ligation has been successfully performed.^{117–119} Some authors have argued that ligation may be preferable over indomethacin as the initial treatment because it is associated with low morbidity and almost certain success.^{120,121} A randomised controlled trial of early surgical ligation demonstrated a lowered incidence of necrotising enterocolitis.¹²² An aggressive approach to ductal closure has been proposed as an effective way to reduce the incidence and severity of chronic lung disease.¹²³ A recent meta-analysis was inconclusive in determining whether medical or surgical intervention was preferable.¹²⁴

Post-operative Complications

Ligation is not a benign procedure, and is oftentimes associated with significant post-operative cardiorespiratory instability. The most common complications include air-leak syndromes, pulmonary oedema,¹²⁵ hypotension requiring vasopressor support,¹²⁶ recurrent laryngeal nerve palsy,¹²⁷ and occasionally ligation of the left pulmonary artery, or even the aorta. Ligation is associated with immediate systolic and diastolic hypertension, which may contribute to reperfusion haemorrhage.¹²⁸ Although improvements in lung compliance immediately following ligation have been recorded,⁸⁰ the post-operative course is characterised by a post-ligation cardiac syndrome consisting of failure of oxygenation due to pulmonary oedema, systolic hypotension, and the need for cardiotropic support, which typically occur 8 to 12 hours after the procedure (Fig. 11-8).¹²⁹ This may relate to altered ventricular loading conditions following ligation.¹³⁰ Surgical ligation in preterm baboons is associated with a significant increase in left ventricular afterload within 12 hours of the procedure, coinciding with the development of left ventricular dysfunction and failure.¹³¹ A number of recent publications highlight an association between ligation and an increased risk of bronchopulmonary dysplasia, severe retinopathy of prematurity, and neurosensory impairment.^{132,133} It is impossible to determine whether this relationship reflects causality, or whether the need for ligation is merely a marker of the severity of illness.

Figure 11-8 Chest radiographs before (A) and 12 hours (B) after patent ductus arteriosus ligation in a 750-g infant who required patent ductus arteriosus ligation. The post-operative chest film demonstrates a significant deterioration with evidence of cardiomegaly and lung oedema suggestive of pulmonary oedema.

Post-operative Care

On the basis of cardiovascular adaptation and other surgical complications, all neonates should be monitored closely in the post-operative period. Specifically, vital signs and urinary output should be carefully monitored, with frequent testing of arterial blood gases and/or lactate. Early commencement of diuretic therapy and increased positive end-expiratory pressure are recommended with failure of oxygenation, and radiologic evidence of pulmonary oedema or atelectasis. Inotropic agents with significant vasoconstrictive activity, such as dopamine or epinephrine, which increase systemic vascular resistance through α -adrenergic mediated mechanisms, should be avoided. Inotropes with afterload-reducing properties, such as dobutamine or milrinone, may be preferable.

Hypotension and Circulatory Collapse

Aetiology of Hypotension or Circulatory Collapse

The nature of the disease processes causing cardiovascular instability is variable, and should be considered when managing treatment. Myocardial dysfunction related to immaturity or elevated systemic vascular resistance and hypovolaemia should be considered as important aetiological factors in the immediate transitional period

(Table 11-3). Beyond the first 24 hours of life the haemodynamically significant duct and sepsis are the most common causes. Hypovolaemia, adrenal suppression, and the effects of raised intrathoracic pressure may present at any stage, and should always be considered. The presence of a duct-dependent obstruction of the systemic outflow tract is just as likely for premature infants, and must be considered, particularly for those in refractory shock.

Hypovolaemia

All neonates require a normal central venous pressure to optimise pulmonary flow. The lack of a relationship between crystalloid support and blood pressure suggests that hypovolaemia is less common than previously considered as a primary aetiological agent. Nevertheless, it should be considered when there is evidence of acute maternal or neonatal blood loss, high insensible losses, or polyuria coinciding with weight loss, where there are major bodily cavity collections of fluid, such as pleural or pericardial effusions or ascites, or where there are excessive gastrointestinal fluid losses due to diseases such as necrotising enterocolitis or short bowel syndrome.

Myocardial Dysfunction

The maturational differences which make the preterm myocardium susceptible to failure have been described in a previous section. These developmental disadvantages make

TABLE 11-3

CAUSES OF HAEMODYNAMIC INSTABILITY IN PREMATURE INFANTS ACCORDING TO THEIR POSTNATAL AGE

Less Than 24 Hours	24 to 72 Hours	Older Than 72 Hours
Myocardial dysfunction, such as increased left ventricular afterload, or sepsis	Haemodynamically significant arterial duct	Haemodynamically significant arterial duct
Hypovolaemia such as birth-related blood loss, or high insensible losses	Myocardial dysfunction, due to, for example, sepsis or asphyxia	Myocardial dysfunction, due to, for example, necrotising enterocolitis, or sepsis
Haemodynamically significant arterial duct	Hypovolaemia, for example due to loss of blood, or insensible losses	Relative adrenal insufficiency
Increased intrathoracic pressure, for example due to pulmonary hyperinflation, or fetal hydrops	Duct-dependent systemic disorder of flow	Post-ligation cardiac syndrome
Duct-dependent systemic disorder of flow	Increased intrathoracic pressure, such as pulmonary hyperinflation	Increased intrathoracic pressure such as lung hyperinflation, pleural or pericardial effusion
		Duct-dependent systemic disorder of flow

the neonatal myocardium vulnerable during a hypoxic-ischaemic insult or when subjected to preload or afterload compromise. The onset of left ventricular dysfunction within 8 to 12 hours of ductal ligation is one example of the intrinsic vulnerability of the immature myocardium to altered loading conditions.¹³⁰ Myocardial dysfunction is also more likely to occur during periods of metabolic acidosis, hypocalcaemia, hypokalaemia, or as a consequence of release of cytokines in the setting of sepsis or necrotising enterocolitis.

Vasomotor Regulation

The immediate postnatal period is characterised by increased systemic vascular resistance upon removal of the placenta from the systemic circuit. The placenta is a low resistance organ, and a rich source of prostaglandins and other inflammatory mediators with vasodilator properties. Beyond the transitional period, the complex regulation of vascular tone involves balancing of vasoconstrictor and vasodilator modifying factors, including nitric oxide, eicosanoids and catecholamines. Septic shock is characterised by increased production of nitric oxide due to upregulation of inducible nitric oxide synthase by endotoxins and tumor necrosis factor- α . Stores of vasopressin are also reduced in septic shock. Both of these factors may contribute to excessive systemic vasodilation and low vascular resistance leading to hypotension. Dysregulation of vasomotor tone should be considered as a possible contributory factor towards circulatory collapse particularly in the presence of isolated low diastolic pressure. The increase in left ventricular exposed vascular resistance following ductal ligation is temporally associated with impaired myocardial performance and low cardiac output. The nature of the vasomotor imbalance is an essential consideration when choosing between vasopressor and vasodilator agents.

Adrenal Gland Suppression

There is accumulating evidence from animal and human studies that the hypothalamic-pituitary-adrenal axis may be dysfunctional in some premature infants, particularly when subjected to stress.¹³⁴ Antenatal administration of multiple courses of steroids may contribute to postnatal impaired adrenal performance.¹³⁵ There is evidence that suboptimal adrenal performance is an important contributor to impaired myocardial performance and impaired cardiorespiratory adaptation in the early neonatal period.¹³⁶ The association between hypotension and levels of cortisol in the plasma is an important consideration, although assessment of the performance of the adrenal glands in clinical practice is challenging.¹³⁴

Therapeutic Approach to Hypotension and Circulatory Collapse

The traditional approach to cardiovascular care is problematic for a number of reasons. First, it has been predominantly pressure based, and fails to consider the importance of systemic blood flow. Second, the approach to intervention is based on regimetal protocols which recommend administration of volume followed by dopamine, dobutamine, and epinephrine.¹³⁷ These protocols do not take into account the nature of the underlying disease, or the acute physiologic disturbance, postnatal maturation, or inter-individual variation. Hence, they lend themselves to incorrect decisions regarding treatment. It is not

logical to treat hypotension secondary to sepsis or congenitally malformed hearts in a similar fashion. It should also be recognised that there is limited clinical evidence to support any current therapeutic agent. In addition there is limited pharmacologic evidence to support the agents currently used in practice. Nevertheless, it is important to understand the mechanism of action, benefits, and limitations of commonly used agents. It is important to recognise that the goal of treatment is to ensure there is adequate oxygenation to meet the metabolic needs of the cell. Both delivery and consumption of oxygen are important considerations (Fig. 11-9). Delivery is influenced by level of circulatory haemoglobin, saturations, and factors which influence myocardial performance, such as preload, afterload, contractility, and heart rate. Consumption is subject to the influence of work of breathing, agitation, and pain.

Volume

There have been no studies of volume versus no treatment. The systematic review of trials of early expansion found no evidence of benefit.¹³⁸ There are two trials, comparing normal saline with albumin, which found no advantage of either therapy in reducing mortality or improving cardiovascular outcomes. Volume should be restricted to treating hypovolaemia where there is an identified precipitating factor, such as acute loss of blood.

Vasopressor Agents

Dopamine is a sympathetic amine and the most commonly used vasoactive agent in the neonatal intensive care unit. It has mixed β -1 and α -adrenergic effects depending on the dose. There is evidence of improved left ventricular performance at levels of less than 2.5 $\mu\text{g/kg/min}$ in immature neonates.^{139,140} It was previously thought that the vasoconstricting effects occur only at doses above 10 $\mu\text{g/kg/min}$. There is evidence of significant α -adrenergic effects in some premature infants at doses as low as 6 $\mu\text{g/kg/min}$, with marked elevation in systemic vascular resistance leading to decreased cardiac output and decreased flow in the superior mesenteric and middle cerebral arteries.¹⁴¹ Whilst dopamine is an effective agent at increasing systemic blood pressure,¹⁴² its effects on systemic flow and end-organ perfusion are concerning. Epinephrine is an endogenous catecholamine produced by the adrenal medulla with similar mixed β -1, at low doses, and α -, at doses greater than 0.375 $\mu\text{g/kg/min}$, adrenergic effects to epinephrine. It is an effective pressor agent in the first 24 hours of life, and may augment cerebral flow.¹⁴³ Its clinical use is normally reserved as a rescue agent, although it may be a more effective pressor agent than dopamine in septic shock or necrotising enterocolitis. High doses or prolonged treatment have been associated with ischaemia and myocardial dysfunction.^{144,145} These effects may relate to direct β -1 adrenergic receptor mediated damage to the myocardium.^{146,147} Vasopressin is a 9-amino acid peptide synthesised in the posterior pituitary, commonly known as anti-diuretic hormone. It displays dichotomous effects through V1 receptors. In the lung, it has pulmonary vasodilator properties via modulation of release of nitric oxide.¹⁴⁸ It acts as a systemic vasoconstrictor, acting through phospholipid complex mediated calcium release. In adults it is a promising systemic vasopressor in vasodilatory shock and cardiopulmonary resuscitation.¹⁴⁹⁻¹⁵¹ Its role in neonatal cardiovascular care is unknown, although theoretically it may be of benefit in restrictive physiologies such as the

Figure 11-9 Factors governing cellular metabolism and the adequacy of tissue oxygenation subdivided according to tissue oxygen delivery and consumption. BP, blood pressure; SVR, systemic vascular resistance.

septal hypertrophy or biventricular hypertrophy that occurs in infants of diabetic mothers.

Inodilator Agents

Dobutamine is a synthetic analogue of dopamine with a predominantly β -1 adrenergic mode of action and minimal α -adrenergic properties. These translate into positive inotropic and afterload reducing effects, which are highly desirable in many neonatal settings e.g. transitional period, post-asphyxial insult, pulmonary hypertension, and following ductal ligation. A systematic review of five randomised controlled trials concluded that dopamine was superior at elevating systemic blood pressure, but there were no differences in survival or neonatal morbidity.¹⁴² Two randomised trials have shown that dobutamine is a more effective agent at improving systemic blood flow.^{152,153} In one study, dopamine was shown to lead to a decrease in left ventricular output. It can be concluded that dobutamine is a more desirable agent for neonates with hypotension and clinical signs of low cardiac output.

Milrinone is an inhibitor of phosphodiesterase III which acts through increasing the bioavailability of cyclic adenosine monophosphate. It is both a systemic and pulmonary vasodilator, with positive inotropic and lusitropic properties. In infants and children undergoing cardiac surgery it has been shown to decrease the combined end-point of death and low cardiac output syndrome.¹⁵⁴ There is also evidence of benefit in neonates with pulmonary hypertension.^{155–157} The pharmacokinetics of milrinone have been characterised in premature infants in the first 24 hours of life.^{158,159} Experimental data suggests that the myocardial effects may be developmentally regulated, with negative inotropy in some species in early gestation.¹⁶⁰ Results of a randomised controlled trial of prophylactic treatment are awaited.

Steroids

These are normally considered as rescue therapy after failure of cardiotropic support. A number of clinical trials have demonstrated improved cardiovascular stability facilitating weaning of cardiotropic drugs after commencement of treatment.^{161,162} The mechanism of action is a combination

of genomic and non-genomic effects. Their merits must be considered in the context of the potential negative effects on myelination and brain maturation.¹⁶³

In summary, the choice of a cardiovascular treatment should consider the nature of the disease, maturational factors, potential effects on both blood pressure and cardiac output (Fig. 11-10), and pharmacological properties. The complications of treatment need also be recognised, which may include tachycardia, increased myocardial consumption of oxygen, hypotension produced by vasodilator agents, regional hypoperfusion produced by vasopressors, impaired myocardial compliance, and arrhythmias.

Pulmonary Hypertension and Prematurity

Until recently, the nature and treatment of pulmonary vascular disease in premature infants have received little attention. It is not recognised that persistent pulmonary vascular disease increases morbidity and mortality associated with chronic lung disease.

	Normal/High BP	Low BP
Normal/High CO	Observe	Pressors (dobutamine, epinephrine, vasopressin)
Low CO	Inodilators (milrinone, dobutamine)	Combination therapy (dobutamine, dopamine, epinephrine)

Figure 11-10 Choice of cardiovascular treatments subdivided according to whether the disturbance affects blood pressure, cardiac output, or both.

TABLE 11-4

CAUSES OF PULMONARY HYPERTENSION IN PREMATURE INFANTS

Acute	Chronic, with Variable Reversibility
Reversible	Chronic lung disease
Respiratory distress syndrome	Chronic patency of arterial duct
Pneumothorax	Congenitally malformed heart
Sepsis	Mild pulmonary hypoplasia
Irreversible	
Pulmonary hypoplasia	
Congenital diaphragmatic hernia	

Aetiology of Pulmonary Hypertension

Persistent pulmonary hypertension of the newborn is the failure of normal postnatal fall in pulmonary vascular resistance leading to problems in oxygenation, right ventricular failure, and/or pulmonary-to-systemic shunting. The regulation of pulmonary vascular resistance represents a balance between vasoconstrictor and vasodilator agents. Pulmonary hypertension is seen both acutely and chronically in premature infants (Table 11-4). This distinction is important, as the responsiveness to pulmonary vasodilator agents is dependent on the degree of pulmonary vascular remodeling. The outcome for neonates with pulmonary hypoplasia is poor. Factors contributing to pulmonary hypoplasia include prolonged rupture of membranes and renal agenesis. Neonates with significant hyaline membrane disease may develop suprasystemic pulmonary arterial pressure, which results in right ventricular loading and, as a consequence of ventricular interaction, impaired left ventricular function. Surfactant rapidly improves oxygenation by reducing pulmonary vascular resistance, which leads to further dramatic changes in pulmonary arterial pressure, right ventricular loading, and left-sided haemodynamics. The mortality rate for preterm infants with pulmonary hypertension, at 26.2%, is six times higher than matched controls.¹⁶⁴

Chronic Lung Disease, Pulmonary Vascular Remodeling, and Pulmonary Hypertension

Preterm lung injury is characterised by injury to both the airspaces and vasculature.¹⁶⁵ The former is characterised by alveolar simplification, whereas the latter is characterised by impaired angiogenesis and pulmonary hypertension. The abnormal pulmonary vascular bed is characterised by increased muscularisation of vascular smooth muscle cells, distal extension of muscle into non-muscularised vessels, and arrested vascular growth. The vasoactivity of pulmonary vessels is characterised by increased basal vascular tone and impaired potential to relax. Factors contributing to pulmonary vascular remodeling include oxygen toxicity, hypoxaemia, and mechanical ventilation.¹⁶⁶ Injury to the pulmonary vascular bed may also play a role in the development of impaired alveolarisation. Pulmonary angiogenesis is modulated by vascular endothelial derived growth factor. The administration of a receptor antagonist leads to impaired angiogenesis and alveologensis in neonatal rodents.¹⁶⁷

Diagnosis of Pulmonary Hypertension in Premature Infants

The diagnosis of pulmonary hypertension in premature infants is challenging, particularly in the presence of lung disease. The signs and symptoms of pulmonary hypertension are non-specific. The electrocardiogram may reveal features of pulmonary hypertension, such as tall P waves and evidence of right ventricular hypertrophy. Cross sectional echocardiography is the gold standard, as cardiac catheterisation is rarely performed. The majority of imaging studies have focused on evaluation of pulmonary haemodynamics in the early neonatal period. The presence of a patent duct and transductal shunting allows more accurate quantification of pulmonary arterial pressure.¹⁶⁸ Magnetic resonance imaging may provide an opportunity to study pulmonary flow and pressure more effectively.

Treatment of Pulmonary Hypertension

The primary treatment is the administration of oxygen; on the basis that hypoxaemia leads to worsening of the pulmonary hypertension. There remains uncertainty as to the most desirable saturation for premature infants. There is some justification for maintaining saturations above 93%.¹⁶⁹ The results of a recent randomised controlled trial of normal versus high saturations suggested a less favorable outcome at higher saturations.¹⁷⁰ Inhaled nitric oxide may be a more desirable therapeutic agent.¹⁷¹⁻¹⁷³ It has also been shown to protect surfactant,¹⁷⁴ and promote both angiogenesis and alveolarisation.¹⁷² These properties suggest it to be an ideal agent for the treatment of pulmonary hypertension and prevention of lung alveolar or vascular injury. Acute administration leads to improved oxygenation in premature infants.^{175,176} The response is developmentally regulated, with few responders less than 28 weeks gestation.¹⁶⁴ In total there have been 11 randomised controlled trials of inhaled nitric oxide in premature infants. Early or late rescue does not reduce the risk of chronic lung disease, improve survival, or long-term outcomes. Early routine use for mildly sick preterm infants seems to reduce the risk of severe cerebral injury, and may improve survival without chronic lung disease.¹⁷⁷ Routine administration in clinical practice is not yet recommended. There is some evidence in support of alternative vasodilator treatments, such as milrinone in premature infants, although there may be an increased risk of intraventricular haemorrhage.¹⁵⁵

Systemic Hypertension and Prematurity

Neonatal hypertension is defined as a sustained systolic blood pressure greater than the 97th percentile for age, gender, and size according to published nomograms. The incidence of systemic hypertension is between 0.2% and 3%.^{178,179} Of these, 9% had indwelling arterial catheters.

Causes of Neonatal Hypertension

In most cases the finding is coincidental on routine monitoring. Occasionally some neonates present insidiously with non-specific symptoms, such as difficulty in feeding, tachypnoea, or lethargy. In more extreme cases, seizures or congestive cardiac failure may occur. It is important to take a thorough history, make a complete cardiovascular evaluation, including testing of blood pressure in all limbs, and to screen for dysmorphisms, ambiguous genital organs, abdominal masses such as Wilms' tumour, and bruits such as produced by renal arterial stenosis. There are many causes

TABLE 11-5

CAUSES OF SYSTEMIC HYPERTENSION IN PREMATURE INFANTS GROUPED AND LISTED IN ORDER OF FREQUENCY OF PRESENTATION

Illness	Cause
Renovascular	Thromboembolism related to catheterisation, renal arterial stenosis, renal venous thrombosis, mid-aortic coarctation, renal arterial compression as caused by severe hydronephrosis
Congenital renal parenchymal disease	Polycystic renal disease, multi-cystic dysplastic renal disease, obstruction at uretero-pelvic junction, unilateral renal hypoplasia or agenesis, congenital nephritic syndrome
Acquired renal parenchymal disease	Acute tubular or cortical necrosis, interstitial nephritis
Drug induced	Dexamethasone, α -adrenergic agents such as dopamine, epinephrine, muscular relaxants, theophylline, ophthalmic drops with phenylephrine
Neonatal abstinence syndrome	Maternal cocaine or heroin
Cardiac	Thoracic coarctation, iatrogenic fluid overload
Endocrine	Congenital adrenal hyperplasia, hyperaldosteronism, hyperthyroidism
Neurologic	Pain, seizures, subdural hematoma
Neoplasia	Wilm's tumour, pheochromocytoma, neuroblastoma

of hypertension, of which renovascular disease and renal parenchymal disease are the most common (Table 11-5).

Treatment of Systemic Hypertension

The urgency of therapeutic intervention with anti-hypertensive drugs is dependent on illness severity. The following general principles should be considered before embarking on specific drug therapy:

- Indwelling arterial catheters should be removed if felt to be causal.
- All current treatments should be re-evaluated as they may be contributory.
- Rapid correction of blood pressure should be avoided, particularly in the early postnatal period, as this may contribute to cerebral ischaemia or haemorrhage.
- It should be the goal of therapy to reduce blood pressure by one-third in the first 6 hours.

Intravenous agents should be used for emergent hypertension. Intravenous diuretics and vasodilators are the mainstay of treatment (Fig. 11-11). Commonly used oral maintenance treatments include diuretics, such as thiazides, inhibitors of angiotensin converting enzyme, except if the neonate exhibits renal impairment, or antagonists of the calcium channel.

CONGENITALLY MALFORMED HEARTS AND PREMATUREITY

The diagnosis and pre-operative care of the preterm neonate with a congenitally malformed heart is challenging as a consequence of the additional effects of immaturity, low birth weight, and other maturational factors. The overall

Figure 11-11 Therapeutic approach to the care of premature infants with systemic hypertension greater than 97th centile.

risk of mortality and pre-operative, peri-operative, and post-operative morbidity is significantly increased, particularly in neonates born with extremely low weight.^{180–183} There is no published data or guidelines on best practice for the management of preterm neonates with congenital cardiovascular malformations. Most of the current practices incorporate best evidence for the care of preterm neonates with treatments normally used for full-term infants. More important, these neonates should be cared for in tertiary neonatal centres with a critical mass of preterm neonates with such malformations, and comprehensive cardiological services.

Echocardiography

The role of cross sectional echocardiography in the care of preterm neonates is twofold: first, to establish the anatomic diagnosis, and second, to monitor patency of the duct, myocardial performance, and pulmonary arterial pressures. Infants born with extremely low weights will often require several echocardiograms before surgical intervention to monitor cardiovascular health and the effects of the cardiac defects on pulmonary arterial pressures.

Cardiovascular Care

The care of the preterm neonate with structural heart disease should focus on those issues related to prematurity and the specific defect. These should not be considered mutually exclusive, nor should they be ranked in terms of the overall care plan, as each influences the other. Care in the early postnatal period is predominantly medical. Surgical interventions or other invasive procedures are normally delayed until the neonate reaches a maturity and weight at which the risks of an expectant approach outweigh the risks of the specific intervention.

Prostaglandin Treatment

Neonates with a duct-dependent cardiac defect require continuous intravenous prostaglandin E_2 therapy to ensure ongoing ductal patency. In the early phase of

stabilisation, the dose required ranges from 0.01 to 0.2 µg/kg/min. Once the clinical and haemodynamic state is stable, the agent is normally weaned to the lowest effective dose to avoid excessive pulmonary vasodilation. This is particularly relevant for neonates with functionally univentricular physiology, where a profound or sustained fall in pulmonary vascular resistance leads to excessive pulmonary blood flow at the expense of systemic perfusion. In many cases, treatment is required for several weeks or months whilst awaiting surgical intervention. This increases the risks of complications related to chronic administration. These include apnoea, gastric outlet obstruction, and hyperostosis.

Monitoring

The stability of the systemic circulation should be assessed first and foremost by careful clinical assessment. Clinical signs of circulatory compromise include tachycardia, hypotension, and decreased urinary output. Plasma lactate, arterial pH, base deficit, and mixed venous oxygen saturations should be monitored as markers of the efficacy of tissue oxygenation. Arterial PaCO₂ and pH should be carefully controlled to avoid excessive pulmonary vasodilation.

Cardiovascular Support

The goal of treatment is to ensure that blood pressure is maintained within a range that sustains adequate systemic perfusion. Treatments should not be administered in any sequential, random, or ranked order but should be given based on the pathophysiology and the likelihood of the treatment to correct the abnormal physiologic state. Therapeutic options include volume expansion, inodilator drugs such as dobutamine and milrinone, or pressors such as dopamine, epinephrine, and vasopressin. Volume expansion is useful in neonates with abnormal right ventricular performance; hence it may play an important role in the care of neonates with elevated pulmonary pressures or duct-dependent pulmonary circulations such as those with pulmonary atresia or severe tetralogy of Fallot. Milrinone has been shown to reduce both mortality and low cardiac output syndrome in post-operative cardiac patients.¹⁵⁵

Interventional

Cardiac catheterisation is occasionally performed. There are some reports in the literature of successful balloon dilation of the pulmonary valve in neonates as small as 690 g and implantation of stents in the left pulmonary artery which had been inadvertently ligated.¹⁸⁴ More commonly balloon atrial septostomy is performed at the bedside in neonates with transposition, or other conditions dependent on a transatrial shunt, such as hypoplastic left heart syndrome.

Surgical Procedures

Decisions related to the optimal timing for surgery are challenging due to the effects of immaturity, low birth weight, and co-morbidities.^{180,181,185–187} Traditionally, an

expectant approach has been preferred. Delaying surgery until immature neonates reach a predetermined maturity and weight increases the risks of pre-operative, peri-operative, and post-operative morbidity. This is particularly the case for neonates with established chronic lung disease. In most centres, the average weight at surgery is between 2000 and 2500 g, although with modified techniques of cardiopulmonary bypass, surgical intervention is attempted at less than 1800 g.¹⁸⁵ Repair of coarctation is also possible in premature neonates as cardiopulmonary bypass is not required. Valvar replacement is rarely performed in premature neonates.

FOCUSED NEONATAL CARE

Respiratory Care

Routine intubation of all neonates when prostaglandins are administered should not be considered to be mandatory, particularly when the diagnosis has been established antenatally and low doses are prescribed. The decision to intubate should be made based on the usual clinical indications. Intubation is recommended in the presence of respiratory failure, clinical signs of cardiogenic shock, the need for cardiotropic support, profound metabolic or lactic acidosis, gestational age less than 28 weeks, and an associated disorder of the airways. One of the most challenging aspects of management is supporting those neonates with evolving chronic lung disease and pulmonary hypertension secondary to pulmonary vascular remodeling. Episodic apnoea, and/or hypoxaemia, occur frequently in these patients, necessitating therapeutic intervention. Oxygen is normally administered to preterm neonates to maintain saturations above 75% due to the risks of tissue hypoxia and adverse neurodevelopmental outcomes.¹⁸⁸ The administration of prophylactic surfactant to those with an antenatal diagnosis of a duct-dependent systemic circulation is not without risk. An excessive fall in pulmonary vascular resistance following administration of surfactant may lead to excessive flow to the lungs at the expense of systemic perfusion. This may be particularly hazardous for neonates with hypoplastic left heart syndrome, where the systemic circulation is extremely tenuous. The radiological confirmation of respiratory distress syndrome is recommended for these neonates before administering surfactant.

Neurological Care

Recent studies using magnetic resonance imaging have identified abnormalities of the cerebral white matter pre-operatively in at least half full-term neonates.^{129,188} There is a strong correlation between these findings and pre-operative arterial tensions of oxygen and blood pressure. The presence of peri-operative hyperthermia or seizures, co-existing genetic abnormalities, or associated defects in other organs, also increases the risk of neurological morbidity. The preterm neonate is even more vulnerable due to the effects of chronic hypoxaemia and intermittent periods of systemic hypoperfusion on the developing brain. In full-term neonates, these events translate into poor long-term neurodevelopmental outcome. There is limited published data on the combined impact of prematurity and a congenital cardiovascular malformation.

Gastrointestinal Care

The risk of necrotising enterocolitis is significantly increased in these neonates, of whom two-fifths had functionally univentricular physiology.¹⁸³ This is most likely to be related to intestinal hypoperfusion and/or chronic hypoxaemia. Extreme immaturity, higher doses of prostaglandin, and episodic low cardiac output syndrome, are also strong predictive factors. These newborns required a focused approach to nutrition that balances the risks of prematurity within the context of a fragile circulation. Wherever possible, guidelines should be developed that focus on the unique needs of such preterm neonates with cardiac disease. Whilst growth is paramount to improve weight, they should be fed cautiously. Expressed breast milk is recommended, and feeds should be increased slowly compared to their normal gestational counterparts.

Miscellaneous

The risk of anaemia is probably increased due to more frequent sampling of blood. Although the threshold for transfusion in preterm neonates remains unclear, it is probably advisable to implement a lower than normal threshold. This is particularly relevant for neonates with functionally univentricular physiology, who are at greater risk of tissue hypoxia. The risk of infection is higher in these preterm neonates, and vigilance is required, as periods of instability are often assumed to be cardiovascular in nature. Due to the challenges of clinical assessment for dysmorphism or genetic abnormalities, routine karyotypic analysis, together with screening for 22q microdeletion, is recommended.

Outcomes

Overall mortality rates of greater than 40% for newborns weighing less than 1500 g, and a doubling of mortality for newborns less than 2.5 kg, have been reported.^{182,183} These reports do not take into account the heterogeneity of the cardiovascular malformations. The literature is severely lacking with respect to long-term outcome in this high-risk population. There are reviews on heterogeneous clusters of preterm neonates with varying types of cardiovascular malformations, but none which focus on any specific defect. Physicians will use the limited information that is available on the outcome for mature infants with certain cardiovascular malformations, and combine this with data for comparable preterm neonates when discussing prognosis. Follow-up data is urgently required for preterm neonates with common cardiovascular malformations so physicians can provide parents with accurate information on the likely course and outcome for their child.

- Martens SE, Rijken M, Stoelhorst GM, et al: Is hypotension a major risk factor for neurological morbidity at term age in very preterm infants? Early Hum Dev 2003;75:79–89.
These two studies address the relationship between systemic blood pressure and abnormal neurological sequelae. The first study concludes that current operational definitions of blood pressure, namely that mean blood pressure approximates gestational age, are not associated with early cerebral injury. The second study demonstrates that any association between hypotension and injury to the white matter is no longer valid when corrected for confounding variables, such as retardation of growth or treatment with steroids.
- Kluckow M, Evans N: Low superior vena cava flow and intraventricular haemorrhage in preterm infants. Arch Dis Child Fetal Neonatal Ed 2000;82:F188–F194.
- Hunt RW, Evans N, Rieger I, Kluckow M: Low superior vena cava flow and neurodevelopment at 3 years in very preterm infants. J Pediatr 2004;145:588–592.
Conventional methods used to assess ventricular output in premature infants are confounded by shunting through the arterial duct. The measurement of flow in the superior caval vein is representative of perfusion of the head and neck, and is not confounded by ductal shunting. An association between critically low superior caval venous flow and early intraventricular haemorrhage has been demonstrated which translates into adverse neurodevelopmental outcomes at 3 years of age.

- Kluckow M, Evans N: Early echocardiographic prediction of symptomatic patent ductus arteriosus in preterm infants undergoing mechanical ventilation. J Pediatr 1995;127:774–779.
The decision to intervene in patients with a patent arterial duct is dependent on the clinical impact. The degree of haemodynamic significance is best predicted by transductal diameter. One important early consequence of systemic-to-pulmonary transductal shunting is systemic hypotension, particularly in neonates weighing less than 1000 g.
- Van Overmeire B, Smets K, Lecoutere D, et al: A comparison of ibuprofen and indomethacin for closure of patent ductus arteriosus. N Engl J Med 2000;343:674–681.
This randomised controlled trial demonstrates equivocal efficacy but less renal side effects with ibuprofen compared to indomethacin.
- Rowland DG, Gutgesell HP: Noninvasive assessment of myocardial contractility, preload, and afterload in healthy newborn infants. Am J Cardiol 1995;75:818–821.
- Moin E, Kennedy KA, Moya FR: Risk factors predicting vasopressor use after patent ductus arteriosus ligation. Am J Perinatol 2003;20:313–320.
- Noori S, Friedlich P, Seri I, Wong P: Changes in myocardial function and hemodynamics after ligation of the ductus arteriosus in preterm infants. J Pediatr 2007;150:597–602.
The sensitivity of the immature myocardium to increased afterload is highlighted in these three studies. In comparison to older children, neonates function at a higher basal contractile state, and impaired myocardial contractility is more likely at higher levels of afterload. The haemodynamic instability that occurs following ligation of the arterial duct is one example of the vulnerability of the immature myocardium to increased afterload.
- Kabra NS, Schmidt B, Roberts RS, et al: Neurosensory impairment after surgical closure of patent ductus arteriosus in extremely low birth weight infants: Results from the Trial of Indomethacin Prophylaxis in Preterms. J Pediatr 2007;150:229–234.
This study was a reanalysis of a subgroup of patients who were recruited for a trial of prophylactic indomethacin. The authors draw an important association between patients who required ligation of the arterial duct and abnormal neurodevelopmental outcomes. It is not possible to determine whether the relationship is causal, or relates to the primary problem of ductal disease.
- Osborn D, Evans N, Kluckow M: Randomized trial of dobutamine versus dopamine in preterm infants with low systemic blood flow. J Pediatr 2002;140:183–191.
- Paradisis M, Evans N, Kluckow M, et al: Pilot study of milrinone for low systemic blood flow in very preterm infants. J Pediatr 2006;148:306–313.
These two studies address the effect of cardiotropic agents on systemic blood flow. Dobutamine is a more effective agent than dopamine at increasing systemic blood flow. Early administration of milrinone prevents low superior caval venous flow.
- Van Meurs KP, Wright LL, Ehrenkranz RA, et al: Inhaled nitric oxide for premature infants with severe respiratory failure. N Engl J Med 2005;353:13–22.
Inhaled nitric oxide is a controversial treatment for hypoxaemic respiratory failure. This study shows a beneficial effect on rates of bronchopulmonary dysplasia and mortality only in neonates weighing more than 1000 g.

- McElhinney DB, Hedrick HL, Bush DM, et al: Necrotizing enterocolitis in neonates with congenital heart disease: Risk factors and outcomes. *Pediatrics* 2000;106:1080–1087.
- Galli KK, Zimmerman RA, Jarvik GP, et al: Periventricular leukomalacia is common after neonatal cardiac surgery. *J Thorac Cardiovasc Surg* 2004;127:692–704.

These studies address the impact of congenital cardiac disease on two important neonatal morbidities. The consequences of critical hypoxaemia and systemic hypoperfusion include cerebral white matter injury, and bowel necrosis. Both of these conditions compromise both survival and long-term neurodevelopmental outcomes.

Pharmacological and Interventional Fetal Cardiovascular Treatment

EDGAR T. JAEGGI and GERALD TULZER

With cross sectional echocardiography providing the means non-invasively to detect and monitor the evolution of anomalies occurring during pregnancy, the fetus has increasingly become the object of intended treatment. This includes the administration of pharmaceutical agents via the maternal circulation or directly into the fetus to control fetal cardiac arrhythmias, to improve congestive heart failure, to treat inflammation and infections and to prevent pulmonary immaturity. Moreover, the increasing ability to use ultrasonic and fetoscopic guidance directly to intervene on the fetus with progressive cardiovascular pathology promises to magnify the advantage offered by prenatal detection of congenital cardiac disease. We will discuss the principles, risks, and contemporary results of intra-uterine fetal treatment for specific cardiac arrhythmias, along with anomalies, which, in the absence of universally accepted guidelines for management, remains a contentious topic among experts.

FETAL ARRHYTHMIAS

Fetal arrhythmia may present as an irregularity of the cardiac rhythm, as an abnormally slow or fast heart rate, or as a combination of irregular rhythm and abnormal heart rate. In most cases, such anomalies as encountered during fetal life present as brief episodes of little clinical relevance. No treatment is usually required. This includes irregularities of the cardiac rhythm caused by blocked and conducted premature atrial contractions. Of more concern are sustained episodes of a cardiac rate that is too fast, greater than 180 beats per minute, or one that is too slow, less than 100 beats per minute. The most common causes for such problems are supraventricular tachycardia, atrial flutter, and severe bradyarrhythmias associated with complete heart block. While a persistently fast or slow rate may be well-tolerated, at the more severe end of the spectrum, it may result in low cardiac output, cerebral damage, fetal hydrops, and death. The finding of arrhythmia-related fetal hydrops is the single most important predictor of adverse fetal outcome. On the other hand, a symptomatic fetal tachyarrhythmia or bradyarrhythmia may respond to, or improve on, pharmacological treatment. Hence, if a disturbance of rhythm is suspected, it is important to determine the likely arrhythmic mechanism, to clarify the impact on the fetal circulation, and to conclude on the urgency and choice of care. Detailed fetal ultrasonic examination provides essential information on the level of fetal activity as an indicator of well-being, on the size and function of the fetal heart,

and the distribution and extent of accumulation of fluid in the fetal pleural, pericardial, and abdominal spaces and the skin. Detailed fetal echocardiography is helpful to detect cardiac tumours, Ebstein's malformation of the tricuspid valve, left isomerism, and congenitally-corrected transposition, all of which may be associated with abnormally fast or slow heart rates. Key to the proper management is a clear understanding of the underlying pattern and mechanism of the arrhythmia. Stepwise analysis of the rate, rhythm, and chronology of atrial and ventricular mechanical events by means of echocardiographic techniques allows the distinction between the different anomalies (Table 12-1). The correct diagnosis will reduce the risk of unnecessary pharmacological treatment, or premature delivery of fetuses with more benign findings, and facilitate the care of those with a major disorder of rhythm. We will discuss in detail those cardiac disorders that might take advantage of transplacental treatment, specifically fetal tachyarrhythmia, fetal thyrotoxicosis, and immune-mediated isolated atrioventricular block and endocardial fibroelastosis.

FETAL TACHYARRHYTHMIA

Mechanisms

A persistent or intermittent fast fetal heart rate is usually the consequence of supraventricular tachycardia, atrial flutter, or sinus tachycardia, with atrial fibrillation, ventricular tachycardia, and junctional ectopic tachycardia as more unusual causes.^{1,2} Supraventricular tachycardia itself can be produced by three different mechanisms, namely atrioventricular re-entrant tachycardia, typically involving the atrioventricular node for antegrade conduction and a fast retrograde ventriculo-atrial conducting accessory pathway, permanent junctional reciprocating tachycardia related to retrograde conduction through the slow pathway of the atrioventricular node, and atrial ectopic tachycardia due to enhanced atrial focal automaticity. These can be distinguished echocardiographically on the basis of the arrhythmic pattern and the ventriculo-atrial time relationships.³ The most common form underscoring fetal tachycardia, atrioventricular re-entry, presents electro-mechanically as a short ventriculo-atrial arrhythmia, the atrium being activated shortly after the ventricles via the fast retrogradely conducting accessory pathway. Re-entry within the atrioventricular node, another potential mechanism of a short ventriculo-atrial tachycardia, is probably rare in the fetus. Therapeutic intervention to terminate atrioventricular or atrioventricular nodal re-entrant tachycardia is aimed at

TABLE 12-1

DIAGNOSTIC ECHOCARDIOGRAPHIC FEATURES OF MORE COMMON FETAL DISTURBANCES OF RHYTHM AND CONDUCTION

	Arrhythmia	A Rate	A-A Interval	AV Relation	V Rate	V-V Interval	V-A Interval	Relevance + Outcome
Irregular rhythm	Isolated PAC, conducted	Normal	Irregular	1:1	Normal	Irregular	Variable	Minor, transient
	Isolated PAC, blocked	Normal	Irregular	>1:1	Normal	Irregular		Minor, transient
Bradycardia	Sinus	75–90	Regular	1:1	75–90	Regular	Long VA	Depends on cause
	Atrial bigeminy, blocked	Normal	Regular irregular	2:1	65–90	Regular		Minor, transient
	2:1 AV block	Normal	Regular	2:1	60–75	Regular		Major, may progress
	Third-degree AVB	Slow–normal	Regular	Dissociated	35–80	Regular	Dissociated	Major, irreversible
Tachycardia	Sinus	160–200	Regular	1:1	160–200	Regular	Long VA	Depends on cause
	AV reentry	190–280	Regular	1:1	190–280	Regular	Short VA	Major, treatable
	Atrial flutter	300–500	Regular	Mainly 2:1	150–250	Mainly regular		Major, treatable
	AET, PJRT	180–230	Regular	1:1	180–230	Regular	Long VA	Major, treatable
	Ventricular (+VA block)	Normal	Regular	<1:1	160–260	Regular–irregular	Dissociated	Major, treatable

A, atrial; AET, atrial ectopic tachycardia; AV, atrioventricular; AVB, atrioventricular block; PAC, premature atrial contractions; PJRT, permanent junctional reciprocating tachycardia; V, ventricular; V-A, ventriculo-atrial; VA block, absence of retrograde conduction via AV node or accessory pathway.

interrupting the balance in timing between the electrical pathways required to sustain the re-entrant circuit.

In long ventriculo-atrial supraventricular tachycardia, which is considerably less common but often more difficult to control when compared to atrioventricular re-entry, the atrial contraction closely precedes the ventricular contraction. This pattern of activation is seen during atrial ectopic tachycardia and permanent junctional reciprocating tachycardia, but also characterises sinus tachycardia. Treatment of atrial ectopic tachycardia aims at the suppression of the ectopic generation of impulses. A variety of treatable conditions occurring during pregnancy may be responsible for sustained sinus tachycardia, including fetal distress, anaemia, infections, maternal β -stimulation, and fetal thyrotoxicosis. The importance of sinus tachycardia is in recognising and treating the underlying cause.

Atrial flutter is sustained by a circular macro-re-entrant pathway that is completely contained within the atrial wall. The atrioventricular node is not part of the re-entry circuit, but serves to transmit the atrial flutter waves to the ventricles. The atrial rate typically exceeds 300 beats per minute, which is sufficiently fast that only every second or third atrial re-entrant wave is conducted through the atrioventricular node, producing ventricular rates of between 150 and 250 beats per minute. Management of atrial flutter aims to terminate the atrial re-entrant circuit, or to delay atrioventricular nodal conduction to achieve a more physiologic fetal heart rate, with improved cardiac filling and output.

Reasons for Fetal Care

There is extensive experience in the management of fetal supraventricular tachycardia and atrial flutter, while data on fetal ventricular tachycardia and junctional ectopic tachycardia is limited to a handful of case reports. Irrespective of the arrhythmic mechanism, three options can be

considered if a fetal tachyarrhythmia is detected. The first is not to attempt treatment. The second option is to institute intra-uterine pharmacological therapy, while the third option is to deliver the fetus and opt for neonatal care. The choice should be based on the condition of the fetus; the characteristics of the arrhythmia in terms of duration, heart rate, and mechanism; the gestational age; the condition of the mother; and the willingness of the mother to undergo treatment. The benefits and risks of the different options must be discussed with both the parents.

In the non-hydrotic fetus with a new diagnosis of an intermittent, or even persistent, tachyarrhythmia after 35 weeks of gestation, observation without anti-arrhythmic pharmacologic therapy may be a safe approach, because hydrops will rarely develop, presumably due to improved intrinsic myocardial properties of the fetal heart during late gestation. On the other hand, pharmacological control of the arrhythmia will facilitate vaginal delivery by allowing the interpretation of the tracings showing the fetal heart rate during labour. If close monitoring without treatment is not feasible, delivery by caesarian section and postnatal conversion to sinus rhythm is the usual choice.

Prior to 35 weeks of gestation, the risks associated with premature delivery probably outweigh the potential hazards of pharmacological treatment to the mother and the fetus. Treatment with drugs aims prenatally to control the disturbance of rhythm in order to prevent or treat fetal cardiac failure. Irrespective of the mechanism of tachycardia and the underlying fetal heart rate, the likelihood of heart failure increases if the tachycardia is incessant and if the fetus has a lower gestational age at diagnosis.⁴ It is well established, nonetheless, that an intermittent arrhythmia pattern may also result in fetal hydrops and death.⁵ As a consequence, intra-uterine treatment with drugs is offered to the majority of fetuses encountered with intermittent and incessant tachyarrhythmia, even in the absence of fetal

compromise. Still, for those cases presenting with only brief and occasional runs of tachycardia in the absence of haemodynamic impairment, abstention from pharmacological treatment and close monitoring for signs of progression may be a valid option, as the arrhythmia often resolves spontaneously.

While antiarrhythmic drugs are usually well-tolerated, some of the most commonly used agents, such as digoxin and flecainide, have narrow margins between levels in the serum that are therapeutic, and those that may be associated with toxicity. In addition, virtually all antiarrhythmic agents have proarrhythmic potentials to provoke new, or to exacerbate existing, arrhythmias. These risks must be factored into a common-sense analysis of risk versus benefit. To our knowledge, no serious maternal complications owing to transplacental or direct fetal anti-arrhythmic pharmacological therapy have been reported thus far in the medical literature. The rate of mortality of treated

non-hydrotic fetuses with supraventricular tachycardia or atrial flutter ranges between 0% and 5%, whereas up to one-fifth of hydrotic fetuses will have a fatal outcome. Comprehensive data on the outcome of untreated fetal tachyarrhythmia is not available.

Treatment

There is no single medication that can safely and effectively convert all fetal tachyarrhythmias to a normal rhythm. In the absence of such a magic bullet, schemes for management are frequently based on personal preferences and experiences, and thus may significantly differ among institutions. In Table 12-2, we illustrate the pharmacokinetics and risks of agents that are commonly used to treat fetal tachyarrhythmias, while in Table 12-3 we list the published experience with first and second lines of drugs used for treatment, discussing these features later in the text.

TABLE 12-2

CARDIOVASCULAR DRUGS USED PRENATALLY, SHOWING THE INDICATIONS FOR TREATMENT, DOSAGES, AND POSSIBLE SIDE-EFFECTS

Drug	Fetal Indications	Dosage and Therapeutic Concentrations	F:M Ratio	Maternal Effects	Fetal and Neonatal Effects
Digoxin	SVT, AF	Oral loading: 0.5 mg q 12h over 2 days Oral maintenance: 0.25–0.75 mg/day TC: 1–2.5 ng/mL	0.8–1 ↓ in hydrops	Narrow therapeutic range; Nausea, anorexia, disturbed vision, fatigue, sinus bradycardia, AV block, VT	Contraindicated in WPW syndrome (not known prenatally)
Flecainide	SVT, AF	Oral 100 mg q 8h (q 6h) TC: 0.2–1 µg/mL	0.7–0.9	Proarrhythmia, blurred vision, nausea, paresthesia, headache, negative inotropy	Proarrhythmia, negative inotropy
Sotalol	SVT, AF, VT	Oral 80 mg q 12h–160 mg q 8h	0.7–2.9	Proarrhythmia, bradycardia, fatigue, hypotension, dizziness	Proarrhythmia, bradycardia
Amiodarone	SVT, VT	Oral loading: 1.6–2.4 g/day for 2–7 days Oral maintenance: 200–400 mg/day Direct: 2.5–5 mg/kg fetal weight IV over 10 min TC: Amiodarone: 1–2.5 µg/mL; DEA: 2 x ↑	0.1–0.3 ↓ in hydrops	Proarrhythmia, bradycardia, lung fibrosis, thyroid dysfunction, hepatitis, photosensitivity; corneal micro-deposits, neuropathy, myopathy	Proarrhythmia, transient thyroid dysfunction, growth restriction
Propranolol	Thyrotoxicosis	Oral 60–120 mg q 6–8h	0.9–1.3	Bradycardia, AV block, fatigue, hypotension, worsening of diabetes, bronchospasm, cold extremities	Growth restriction, bradycardia, respiratory depression, hypoglycemia
Propylthiouracil	Thyrotoxicosis	Oral 50–200 mg/day Aim: lowest effective dose to maintain maternal FTI in high normal range	1.9	Agranulocytosis, nausea, vomiting, loss of taste, skin rash, itching, drowsiness, dizziness, headache	Risk of hypothyroidism; goiter
Dexamethasone	Immune-mediated AV block; EFE	Transplacental: 8 mg/day for 2 weeks; 4 mg/day – 30 weeks; 2 mg/day – delivery Postnatal (for carditis and EFE): prednisone for 6–8 weeks	0.3	Adrenal gland suppression, weight gain, fluid retention, hypertension, mood changes, insomnia, irritability, striae, hair growth, diabetes, impaired wound-healing, susceptibility to infections	Oligohydramnios, growth restriction, impaired wound-healing, (?) delayed brain development
β-agonists	Immune-mediated AV block	Oral salbutamol: 10 mg q 8h (–6h) (maximal dose: 40 mg/day) Oral terbutaline: 2.5–7.5 mg q 4–6 h (maximal dose: 30 mg/day)	0.5	Palpitation, tremor, diaphoresis, dyspnea, hyperglycemia, chest pain, nausea, nervousness, dizziness, arrhythmias	Neonatal hypoglycemia
Immune-globulin	Immune-mediated AV block; EFE	Maternal: 1 g/kg IVIG every 2–3 weeks (maximal dose: 70 g/dose) Neonatal: single dose of 1 g/kg IVIG + prednisone for 6–8 weeks	↑ with age	Headache, chest pain, fever, chills, nausea, malaise, anaphylaxis (rare), aseptic meningitis	Not reported

AF, atrial flutter; AV, atrioventricular; DEA, desethylamiodarone; EFE, endocardial fibroelastosis; FTI, free thyroxine index; F:M ratio, fetal to maternal fetal ratio; IVIG, intravenous immunoglobulin; SVT, supraventricular tachycardia; TC, therapeutic concentrations; VT, ventricular tachycardia.

Because of the risk of hazardous complications, each antiarrhythmic treatment other than digoxin should probably be started in an inpatient setting to allow serial monitoring of the maternal electrocardiogram and the fetal cardiac rhythm. To exclude unsafe maternal conditions, such as long-QT syndrome for class III agents, or ventricular pre-excitation for digoxin, the pregnant mother should undergo a detailed medical examination, a 12-lead electrocardiogram, and testing of the electrolytes in the maternal serum prior to administration of any medication. Thyroid function should be checked if fetal hyperthyroidism is suspected, or if treatment with amiodarone is considered. The risk of dangerous side-effects may be further reduced by restricting treatment whenever possible to a single agent, and by avoiding excessive dosages, toxic concentrations, or potentially hazardous combinations, if additional pharmacological treatment is required.

Choice of Drug

A clear understanding of the pharmacokinetics, actions, and indications of the handful of clinically relevant pharmaceuticals is essential if the tachycardia is to be treated efficiently and safely.

Digoxin

Digoxin is the preferred choice for fetal atrioventricular re-entrant tachycardia and atrial flutter in the absence of fetal hydrops. The drug has two main effects. First, it induces vagal slowing of the sinus node and atrioventricular nodal conduction, and second, it enhances myocardial contractility. The positive inotropic effect is the result of an inhibition of the sodium-potassium adenosine triphosphatase pump, which leads to an increase in the level of sodium ions in the myocytes, triggering a rise in the intracellular level of calcium ions by the exchange of sodium and calcium ions.

Dosing and Pharmacokinetics

Oral or intravenous maternal digoxin loading is recommended for more urgent fetal indications. A standard oral loading dose of digoxin is 0.5 mg given twice daily for 2 days, followed by a maintenance dose of from 0.25 to 0.75 mg daily, aiming at achieving maternal concentrations at the upper therapeutic range, namely 2 to 2.5 ng/mL. When no loading dose is given, steady-state concentrations are achieved after 5 to 7 days on maintenance therapy. Approximately four-fifths of the tablet form is absorbed from the gastrointestinal tract, and one quarter of the drug is bound to plasma proteins. Elimination occurs via the kidneys, and adjustment of dosage is required in the setting of maternal renal failure. Digoxin readily crosses the placenta, reaching similar concentrations in the fetal and maternal serums. The transplacental passage of the drug is hampered in the setting of fetal hydrops, and adequate levels are usually not obtained in the fetal serum.⁶

Interactions

There are numerous known interactions, including those with amiodarone and flecainide, both of which increase the levels of digoxin.

Adverse Effects and Precautions

Use of digoxin is contraindicated in the settings of Wolff-Parkinson-White syndrome, higher-degree atrioventricular block, and hypertrophic obstructive cardiomyopathy.

The incidence of undesired symptoms correlates with the concentration of the drug achieved in the plasma. In the elderly adult treated with digoxin for cardiac conditions, adverse effects include loss of appetite, nausea, vomiting, diarrhoea, blurred vision, confusion, drowsiness, dizziness, nightmares, agitation, and depression. Uncommon symptoms are acute psychosis, delirium, amnesia, atrial or ventricular tachycardia, and atrioventricular block. No major adverse events have been reported during pregnancy.

Treatment of the Fetus

Successful transplacental treatment of fetal supraventricular tachycardia with digoxin was first reported in 1980.^{7,8} The first larger case series reporting efficacy in reversing fetal supraventricular tachycardia to a normal rhythm was published 5 years later,⁹ conversion to a normal rhythm being achieved in seven-tenths of cases with digoxin given either alone to the mother, or in combination with another antiarrhythmic drug. Similar results were obtained by others,^{3,10-14} albeit that the rate of success declined to one-tenth if there was fetal hydrops.¹⁰ Apart from fetal hydrops, digoxin administered transplacentally is less effective for atrial ectopic tachycardia and permanent junctional reciprocating tachycardia, while it is most efficient in atrioventricular re-entrant tachycardia.^{3,15} The drug slows atrioventricular conduction and the rate of tachycardia in fetuses with atrial flutter, but is less likely to restore a normal cardiac rhythm when compared to sotalol alone, or to the combination of digoxin and sotalol.^{16,17} Digoxin, therefore, is a safe and reasonably efficient first line of transplacental therapy for atrioventricular re-entrant tachycardia, the most common cause of persistent fetal tachycardia. In the presence of hydrops, atrial flutter, atrial ectopic, and permanent junctional reciprocating tachycardia, class 1c or class III agents either alone, or combined with digoxin, are more effective therapeutic choices.

Flecainide

Flecainide is the most extensively used class Ic agent for treatment of fetal supraventricular tachycardia. The drug blocks slow sodium channels, causing prolongation of the cardiac action potential. The electrophysiological effect is slowing of the electrical conduction in the His-Purkinje system and ventricular myocardium, along with reduction in ventricular contractility. The blocking effect on the cardiac sodium channels increases as the heart rate increases. This means that flecainide is potentially most useful to break an abnormal rhythm associated with a rapid heart rate.

Dosing and Pharmacokinetics

To treat a fetal arrhythmia, the standard oral dosage of flecainide is 300 mg/day, given in three doses. The drug is well-absorbed, and peak levels are obtained within 2 to 4 hours. A small amount of the drug is bio-transformed in the liver to nearly inactive metabolites. Flecainide is primarily excreted in the urine. The drug crosses the placenta readily, even in the presence of fetal hydrops.^{18,19} Therapeutic levels in the mother are reached within 3 days of commencing treatment.

Interactions

There are numerous interactions with other agents. Amiodarone, for example, may increase the levels of flecainide by inhibiting cytochrome 450, which is used to metabolise flecainide. Flecainide increases the concentration of digoxin by about one-fifth.

Adverse Effects and Precautions

Flecainide depresses cardiac performance, particularly in patients with compromised myocardial function. The chance of proarrhythmia increases in the presence of major structural cardiac disease, ventricular dysfunction, ventricular arrhythmias, and hypokalemia.^{20,21} Thus, flecainide should be avoided in individuals with any of these conditions. Flecainide can safely be used in predominantly healthy mothers carrying fetuses with supraventricular tachycardia.²² Adverse events such as blurred vision, dizziness, headache, nausea, paresthesia, fatigue, tremor, and nervousness were uncommon in a placebo-controlled trial.²³ No major maternal side-effects are reported.^{12–14,24}

Trans-placental Treatment

When used as the drug of choice, flecainide controlled supraventricular tachycardia and atrial flutter in two-thirds of cases.^{10–12,14,18} This improved to almost four-fifths if a second antiarrhythmic drug was added.¹⁴ No maternal adverse effects were observed, but one-quarter of fetuses died either during fetal life or as neonates. Severe fetal bradycardia causing death was observed in one fetus with only mild ascites shortly after commencing treatment with flecainide.¹⁴ Control in excess of nine-tenths of cases was observed when flecainide and digoxin were used in combination.^{13,24} When given at therapeutic doses, therefore, flecainide provides safe and effective treatment for fetal supraventricular tachycardia. When flecainide was the preferred choice to treat hydropic fetuses, however, around one-sixth of fetuses died in the perinatal period.

Sotalol

Sotalol is used to treat both fetal supraventricular tachycardia and atrial flutter. No data exist on its use in fetal ventricular tachycardia. The actions of sotalol include those of both class II agents, providing non-selective β -blockade, and class III effects, with prolongation of the duration of the cardiac action potential. The drug inhibits inward potassium channels, progressively prolonging refractoriness of the working myocardial and conduction tissues at slower heart rates.²⁵ Clinically, this may mean that the prolongation of the action potential is more effective at preventing the initiation of a tachycardia than in terminating one once established. Sotalol exhibits a positive inotropic effect, particularly at a slower heart rate.²⁶ The β -blocking potency of sotalol is up to half of that of propranolol when compared milligram per milligram. Beta-blockade decreases the heart rate, and delays atrioventricular nodal conduction.

Dosing and Pharmacokinetics

To treat the fetus, the typical starting dose given to the mother is 160 mg per day, given in two doses. If there is fetal hydrops, we would commence with 320 mg per day, either alone or in combination with digoxin. If there is no conversion to a normal rhythm within several days of administration, we would increase the dose further to a maximal daily level of 480 mg, given in three doses. The drug is completely absorbed and peak concentration in the plasma is reached within 2 to 4 hours of oral administration. The compound is secreted in the urine, and it may be necessary to regulate the dose in mothers with renal failure. Placental transfer is excellent, and the drug does not accumulate in the fetus.²⁷

Adverse Effects

The most feared adverse effect is torsade de pointes, which may present with a range of clinical symptoms from palpitations to syncope to sudden death. The incidence of

ventricular proarrhythmia in adults with supraventricular tachycardia is less than 2%. Probably the most effective way to prevent maternal proarrhythmia is by avoiding excessive prolongation of the QTc interval.²⁵ The prevalence of maternal electrocardiographic changes is unknown, but no significant prolongation of the neonatal QTc interval has been found after administration of up to 480 mg per day to the mother for treatment of fetal supraventricular tachycardia.²⁷ Adverse effects related to the β -blocking properties include arterial hypotension, bradycardia, worsening of asthma or obstructive lung disease, depression, fatigue, insomnia, and impaired sexual function. Its safety was assessed in a randomised, double-blind trial in adults,²⁸ with one-twentieth of patients discontinuing the drug because of side-effects related to β -blockade.

Treatment of the Fetus

When used as a first line agent, the drug controlled supraventricular tachycardia and atrial flutter in two-thirds of fetuses.^{15,17,27} Higher rates of conversion to a normal rhythm were observed when sotalol was started jointly with digoxin when the arrhythmia was diagnosed, or eventually used as a combination to treat resistant supraventricular tachycardia.^{3,17,19,29} Transient maternal side-effects, such as nausea, dizziness, and fatigue, were reported in one-tenth of mothers.¹⁷ Conflicting data exist on the role in the fetus, even from the same investigators.^{17,27} When used as a first line agent, however, the drug was shown to convert over nine-tenths of fetuses with supraventricular tachycardia or atrial flutter to a normal rhythm. Sotalol, therefore, is an efficient and safe drug with which to treat fetal supraventricular tachycardia and atrial flutter when there are no maternal contraindications to its actions. The overall rate of perinatal death in fetuses treated with transplacental sotalol was 18%.

Amiodarone

Amiodarone has mainly been used to treat drug-resistant fetal tachyarrhythmias associated with cardiovascular compromise. There is considerable data documenting its efficacy and reasonable safety in children and adults with supraventricular and ventricular tachycardias. The drug, which acts by blocking the potassium channels, lengthens the duration of the action potential and cardiac refractoriness at all heart rates. It also acts to produce β -blockade, to block the L-type calcium channels, and to slow His-Purkinje and myocardial conduction at rapid heart rates. It does not affect ventricular contractility.

Dosing and Pharmacokinetics

To achieve therapeutic fetal concentrations, oral loading doses of from 1600 to 2400 mg per day are given to the mother for from 2 to 7 days, followed by maintenance doses of 200 to 400 mg per day.^{14,30,31} The drug has unusual pharmacokinetics, with absorption of the drug given orally ranging from one-third to two-thirds, and peak concentrations in the plasma being reached within 3 to 7 hours of ingestion. Amiodarone is metabolised in the liver to its major metabolite, desethylamiodarone, which also has antiarrhythmic properties. Because of their lipophilicity, the compounds accumulate in many tissues, including fat, liver, lung, skin, and myocardium. Excretion is predominantly via shedding of epithelial cells of the skin and gastrointestinal tract. The half-life for elimination is between 3 and 10 days for the first 50% of the drug, and is then slower due to slowed release from tissue stores.

As a consequence, clinically important levels may persist for several months following cessation of administration. Amiodarone and desethylamiodarone incompletely cross the placenta to the fetus, with only one-sixth reaching the fetus for amiodarone, albeit a somewhat higher ratio existing for desethylamiodarone.³² Transplacental transfer is reduced still further in hydropic fetuses.³³

Interactions

Amiodarone interferes with the pharmacokinetics of a large variety of drugs, such as digoxin, class Ic agents, tricyclic antidepressants, and general anaesthetics. Doses of most other drugs need to be reduced in individuals taking amiodarone.

Adverse Effects

Amiodarone has numerous side-effects. The most serious reaction is interstitial lung disease, which occurs in up to one-tenth of adults receiving doses of amiodarone greater than 400 mg per day over prolonged periods of time. Pulmonary fibrosis has also been documented during therapy at low doses and short duration. Clinical findings suggesting pulmonary toxicity include coughing, dyspnea, fever, chest pain, high sedimentation rates, and bilateral lung infiltrates. If diagnosed at an early stage, the disease may be reversible. Due to the high iodine content, and the structural similarity of amiodarone to thyroxine, thyroid dysfunction is common, being found in almost one-tenth of chronically treated individuals. Asymptomatic, reversible corneal microdeposits are almost universally present if the drug is taken for at least 6 months. Hepatitis may also occur. As a precaution, periodic ophthalmic, hepatic and thyroid function tests are recommended for patients receiving amiodarone. There is a low risk of torsade de pointes, which can be minimised by keeping the QTc interval in a near-normal range. Adverse fetal effects attributable to amiodarone include congenital hypo- and hyper-thyroidism, retardation of growth, bradycardia, and prolongation of the QTc interval.

Treatment of the Fetus

Transplacental amiodarone has been shown to restore sinus rhythm in two-thirds of hydropic fetuses with drug-refractory tachyarrhythmias.^{14,31} Of the treated fetuses, one-twentieth died, and side-effects serious enough to withdraw the drug occurred in one woman, who suffered photosensitivity dermatitis and thrombocytopenia. Transient biochemical signs of thyroid dysfunction were seen in one-fifth of both fetuses and mothers. Other maternal side-effects were mild sinus bradycardia and transient incomplete atrioventricular block during loading with the drug. Because of the maternal and fetal risks, therefore, amiodarone should be reserved for drug-refractory fetal tachyarrhythmias in hydropic fetuses with ventricular dysfunction.

Direct Fetal Treatment

Direct fetal treatment is reserved for the rare, severely hydropic fetus with a drug-refractory tachyarrhythmia. As mentioned previously, the transplacental transfer of some antiarrhythmic agents is significantly hampered in the presence of fetal hydrops, and thus therapeutic levels of drugs may not be reached even with toxic maternal doses. To overcome this problem, repeated intravenous, intramuscular and intraperitoneal fetal injections of amiodarone, digoxin and adenosine, in addition to the conventional therapy, has been successfully performed to resolve multi-drug

refractory fetal tachyarrhythmia complicated by fetal hydrops.^{33–38} Direct intravenous adenosine may instantly terminate re-entrant supraventricular tachycardia, but because of its short duration of action, direct treatment should be combined with a longer acting antiarrhythmic agent. Amiodarone seems to be predestined for the direct use, both because of its efficiency and long-half life, limiting the number of invasive fetal procedures that are required to maintain therapeutic levels.

Other Antiarrhythmic Agents

Other antiarrhythmic agents, such as verapamil, procainamide, and quinidine are no longer used for prenatal therapy, because of substantial side-effects in both mother and fetus, and/or insufficient antiarrhythmic actions. By contrast, maternal intravenous infusion of magnesium and lidocaine, a blocker of the sodium channel that shortens the duration of the QT interval, has been used to suppress fetal torsades de pointes associated with congenital long QT syndrome diagnosed prenatally by fetal magnetocardiography.³⁹

Summarising the published results, digoxin remains a drug of choice in the treatment of fetal atrioventricular re-entrant tachycardia in the absence of fetal hydrops, although some centers nowadays favour more potent and equally safe medication. In terms of converting atrial flutter to sinus rhythm, sotalol appears to be more effective than digoxin. In the setting of fetal hydrops, a class Ic or class III drug, either alone or in combination with digoxin, is the preferred treatment for supraventricular tachycardia, with the most favourable outcomes reported for amiodarone. The primary use of amiodarone, an antiarrhythmic agent with no negative inotropy, should be considered if the fetal myocardial contractility is severely hampered. Control of the rate of tachycardia, or conversion to sinus rhythm, is achieved in the majority of cases within a few days of transplacental treatment with a single drug, or with combinations of therapeutic agents. Once the arrhythmia is under control, the antiarrhythmic treatment is usually maintained to birth, with weekly monitoring of the fetal heart rate to detect arrhythmic recurrence. If supraventricular tachycardia recurs spontaneously after birth, or is easily inducible, for example by transoesophageal electrophysiological study, the antiarrhythmic treatment, usually with a β -blocker, will be continued for at least 6 to 12 months. In up to one-fifth of infants, the supraventricular tachycardia will persist beyond 1 year of age. In contrast, postnatal recurrence of atrial flutter is uncommon, and antiarrhythmic long-term prophylaxis is usually not required.^{16,40}

FETAL THYROTOXICOSIS

Thyrotoxicosis, induced by maternal thyroid-stimulating antibodies, should always be considered if the fetus of a mother with active Graves' disease, or with a history of Graves' disease, presents with a persistent tachycardia of 180 to 200 beats per minute. Other findings in the fetus include hydrops, restriction of growth, and goiter.⁴¹ Fetal ultrasonography is helpful in assessing both the fetal goiter and growth. The diagnosis of maternal Graves' disease is suggested by physical signs, such as prominent eyes, an enlarged thyroid gland, and exaggerated

reflexes, and is confirmed by finding markedly elevated levels of thyroid hormone. Because fetal tachycardia and restricted growth may result from other pathological processes, some have advocated sampling of umbilical blood to measure the levels of thyroid-stimulating antibodies, thyroid-stimulating hormone, and FT_4 for definitive diagnosis.⁴² The risk of fetal mortality and severe complications is high if thyrotoxicosis goes unrecognised and untreated.

Treatment

The mainstay of prenatal treatment is inhibition of the excessive fetal synthesis of thyroid hormone by propylthiouracil and slowing of the fetal heart rate by β -blockade (see Table 12-2).

Propylthiouracil

Propylthiouracil does not affect the release of thyroxine, and therefore the rapidity of response to treatment depends on the amount of colloid stored in the thyroid gland. The drug is generally well-tolerated, with side-effects occurring in about 1% of treated adults. Adverse events are mainly related to the skin, and include rash, itching, abnormal loss of hair, and dermal pigmentation. Agranulocytosis, nausea, vomiting, loss of taste, joint or muscle aches, numbness and headache are other possible reactions. The agent crosses the placenta and may produce fetal hypothyroidism even if administered in relatively low doses.⁴² To limit the risk, treatment with propylthiouracil should be titrated to the lowest possible dose to maintain the maternal index for free thyroid in the high normal range. The fetal response can be monitored by serial measurement of the fetal heart rate, and by direct measurement of T_4 and thyroid-stimulating hormone in the fetal cord blood. Ultrasonography may permit assessment of changes in the size of the thyroid gland. Infants born to mothers with Graves' disease should be closely followed by a paediatrician to assess any thyroidal dysfunction. No long-term effects on intellectual or physical development from propylthiouracil or drug-induced hypothyroidism have been reported.⁴³

Propranolol

Maternal propranolol, or a similar β -blocker, is used to slow the fetal sinus tachycardia, thus reducing the risk of high-output cardiac failure. Propranolol is rapidly and completely absorbed, with levels peaking in the plasma from 1 to 3 hours after oral ingestion. Despite complete absorption, propranolol has a variable bioavailability due to extensive hepatic first-pass metabolism. The agent is highly lipophilic, achieving high concentrations in the brain. The commonly observed side-effects of the drug are explained by spasm of smooth muscle, exaggerated cardiac actions, and effects on the central nervous system. Beta-blockade is contraindicated in the presence of severe bradycardia, high-degree atrioventricular block, severe asthma, or bronchospasm, Raynaud's phenomenon, and other peripheral vasculopathies. The drug readily crosses the placenta. Pharmacological β -blockade is considered relatively safe for the fetus, although a number of side-effects have been reported in neonates following the use of propranolol in pregnancy. These include restricted growth, hypoglycemia, bradycardia, and respiratory depression.⁴⁴ Thus, newborns of women consuming the drug close to delivery should be

observed during the first days of life for symptoms of excessive β -blockade.

IMMUNE-MEDIATED FETAL ATRIOVENTRICULAR BLOCK

Atrioventricular block refers to a disturbance of the normal conduction of the electrical impulse through the atrioventricular node, the bundle of His, and/or the bundle branches. Depending on the severity of the blockage, the conduction is either delayed, producing first-degree atrioventricular block, intermittently conducted, giving second-degree block, conducted in alternative fashion to produce 2 to 1 atrioventricular block, or completely interrupted, producing third-degree block. Complete atrioventricular block, with independently beating atriums and ventricles, is the most common fetal presentation of conduction disorders, accounting for almost two-fifths of major fetal arrhythmias. The cardiac output is compromised by the slowed ventricular rate, by the loss of the normal atrial contribution to ventricular filling, and by co-existing structural or functional cardiovascular pathology.

In roughly half of prenatally diagnosed cases, complete atrioventricular block is associated with left isomerism of the atrial appendages or congenitally corrected transposition.^{45,46} Conduction block associated with structural heart disease results from anatomical discontinuity of the electrical conduction system, either due to an initial lack of fusion of the atrial and ventricular components, or due to a secondary interruption of the atrioventricular conduction axis.⁴⁷⁻⁴⁹ The outcome of left isomerism complicated by congenital complete heart block is particularly poor, with less than one-tenth of afflicted fetuses surviving to infancy. Transplacental treatment with a β -sympathomimetic agent to increase the fetal cardiac output has not improved the outcome of these fetuses.^{45,46,50-52}

In some fetuses having heart block without congenital cardiac disease or maternal auto-antibodies, interruption of the His bundle was found on necropsy.⁵³ As an isolated disorder, nonetheless, congenital atrioventricular block is strongly linked to mothers with auto-antibodies to 48-kDa SSB/La, 52-kDa and/or 60-kDa SSA/Ro ribonucleoproteins. These antibodies are prevalent in nearly 2% of predominantly asymptomatic pregnant women.⁵⁴ The maternal IgG antibodies increasingly enter the fetal circulation during gestation, and may elicit an immune-mediated reaction, resulting in the progressive destruction of the fetal atrioventricular node, cardiac and extracardiac inflammation, endocardial fibroelastosis, and dilated cardiomyopathy in the susceptible offspring.^{45,55,56,57} Diffuse deposition of immune-globulins, and infiltration of T-cells throughout the myocardium, leading to endocardial fibroelastosis, may occur in the absence of congenital heart block.⁵ Complete atrioventricular block, the most common cardiac manifestation, affects about 1% to 2% of antibody-positive mothers, while the risk of recurrence for subsequent fetuses ranges from one-tenth to one-fifth.^{55,58} Complete atrioventricular block is most commonly detected between 20 and 24 weeks of gestation, but a presentation later during the course of pregnancy, or even after birth, is not exceptional.⁵⁵ To this day, there is no reliable marker that predicts which fetus, in the absence of early anomalies, will eventually develop immune-mediated complications.

Reasons for Treatment

Untreated fetuses with isolated congenital complete atrioventricular block have a perinatal mortality of up to two-fifths.^{45,53,55,59} Risk factors for death included the echocardiographic documentation of fetal hydrops, endocardial fibroelastosis, a ventricular rate below 55 beats per minute, as well as premature delivery. Hydrops, endocardial fibroelastosis, and/or a heart rate below 55 beats per minute were found in one-tenth, one-quarter, and two-fifths, respectively, of fetuses referred with isolated complete atrioventricular block to the Hospital for Sick Children, Toronto, between 1990 and 2003.⁶⁰ In one-quarter of the more severely affected cases, symptoms associated with a poor outcome became apparent, or developed, only later in pregnancy. The diagnosis of antibody-mediated myocarditis, hepatitis, and dilated cardiomyopathy was made only after delivery in cases that had been managed without prenatal anti-inflammatory treatment. These factors have led to the routine use of dexamethasone in pregnancies complicated by isolated fetal complete heart block.⁶⁰ The routine administration of transplacental glucocorticoids for fetal atrioventricular block, however, is controversial, because of concerns of toxic steroid effects on the developing fetus, and because survival is often possible without prenatal intervention. Thus, an alternative approach could be to restrict transplacental treatment to the compromised fetus.^{51,61} On the other hand, the value of such an approach is unknown apart from a handful of anecdotal case reports.

Choice of Treatment

Different prenatal strategies have been attempted with variable success, including the use of fluorinated steroids, immunoglobulin, plasmapheresis, β -inotropic agents, and pacing, either to prevent or treat immune-mediated fetal inflammation, and/or to augment fetal cardiac output. Direct ventricular pacing is technically possible, though it failed to prevent fetal death in the two cases for which it was attempted more than a decade ago. Similarly, premature delivery for immediate pacing has not been a satisfactory approach in our experience, nor in that of others, as it places the infant at the additional risks and complications of prematurity. To date, evidence of clinical usefulness has been provided only for fluorinated steroids and β -agonists (see Table 12-2). Repeated maternal injections of immunoglobulin could become a useful adjunct to lower maternal levels of antibodies, and to block their pathologic expression on the fetal heart.

Dexamethasone and Betamethasone

Dexamethasone and betamethasone are potent synthetic glucocorticoids that are only minimally metabolised by the placenta and easily pass to the fetus, making these agents useful for direct fetal treatment. Use of steroids in the treatment of isolated fetal atrioventricular block is based on the assumption that the aetiology of conduction disease is an inflammatory carditis, and that the transplacental administration of steroids may help to temper the immune-mediated tissue damage.⁶² Access to the Research Registry for Neonatal Lupus then permitted study of a series of mothers with anti-Ro/La antibodies and offspring with atrioventricular block.⁶³ None of the fetuses with complete heart block responded to the transplacental treatment with steroids with an improvement of the conduction anomaly,

Figure 12-1 The impact of transplacental fetal treatment with (Steroid) and without (No Steroid) dexamethasone on fetal and postnatal outcome. The survival was best with the protocol-guided approach (Tx Protocol) introduced in 1997. (Reproduced with permission from Jaeggi ET, Fouron JC, Silverman ED, et al: Transplacental treatment improves the outcome of prenatally diagnosed complete atrioventricular block without structural heart disease. *Circulation* 2004;110:1542–1548.)

and three treated fetuses with incomplete third-degree atrioventricular block progressed to complete block. Of treated fetuses with second-degree block, four reverted to first-degree block, with two remaining in first-degree block at 4 years of age. Transplacental treatment with steroids has also resulted in resolution of effusions and fetal hydrops.^{53,63–68} This type of response is often observed without any improvement in heart rate, implying that accumulation of fluid in the fetus may result from immune-mediated serositis rather than cardiac failure.

There has been an improvement in outcome for fetuses with complete atrioventricular block (Fig. 12-1) simultaneous with the introduction of perinatal guidelines for treatment (Fig. 12-2).⁶⁰ At the time of diagnosis of atrioventricular block, oral dexamethasone was given in high doses and, when possible, maintained for the duration of the pregnancy. If the average fetal heart rate declined below 50 to 55 beats per minute, or if the cardiac function was reduced, a β -sympathomimetic agent was added. Pregnancies were monitored weekly by a closely collaborating team of fetal cardiologists, rheumatologists, and obstetricians. Delivery was arranged at around 37 weeks of gestation

Figure 12-2 The protocol used for the management of immune-mediated fetal complete atrioventricular block at the Hospital for Sick Children. DXMT, dexamethasone; HR, heart rate. (Reproduced with permission from Jaeggi ET, Fouron JC, Silverman ED, et al: Transplacental treatment improves the outcome of prenatally diagnosed complete atrioventricular block without structural heart disease. *Circulation* 2004;110:1542–1548.)

in uncomplicated pregnancies, and the neonate was then transferred to the intensive care unit. Prior to 1997, pregnancies with isolated heart block had typically been followed by serial echocardiography, but without attempts to alter the perinatal outcome by transplacental fetal therapy. Survival of fetuses diagnosed prior to 1997 was 80% at birth, and 47% at 1 year, but thereafter this improved to 95% (see Fig. 12-1). Immune-mediated conditions causing postnatal death or requiring cardiac transplantation were only observed in fetuses surviving from untreated pregnancies. Prolonged administration of dexamethasone, therefore, may render a fetus with isolated complete atrioventricular block less likely to develop other disease-related manifestations such as myocarditis, cardiomyopathy, and/or hydrops, thus improving overall outcome.

We have now modified the guidelines to minimise the risk of severe oligohydramnios in the last trimester. Dexamethasone, which is now started at 8 mg per day, is reduced to 4 mg per day after two weeks, and then to 2 mg per day at around 30 gestational weeks. Moreover, maternal intravenous immunoglobulin is usually added if we detect ventricular endocardial fibroelastosis, ventricular dysfunction, and/or incomplete atrioventricular block.

Effects of Steroids on the Developing Fetus

Dexamethasone and betamethasone have been given to humans and animals in a wide range of dosages, at different gestational ages, and for various indications. While in fetuses with heart block the daily exposure does not exceed 0.05 mg per kg, the treatment is maintained over several weeks. Higher dosages were used in animal studies, for prenatal human pulmonary maturation, and for the postnatal treatment of respiratory distress syndrome. With the caveat that the published data may not be applicable to the fetus with complete atrioventricular block, steroids that cross the placenta have been shown to affect birth weight and the central nervous system with single and repeated prenatal steroid administration. Reduction in birth weight has been

seen in sheep,⁶⁹ non-human primates,⁷⁰ and humans.^{60,71,72} The effects on growth are more dramatic with multiple doses. Not unexpectedly, one-quarter of our newborns with isolated heart block were growth-restricted after prolonged transplacental exposure to steroids. Few, if any, other adverse effects on the fetus during the human pregnancy, however, have been documented. Neuroimaging of preterm human infants exposed to a single steroid course for lung maturation suggests a reduced incidence of intraventricular hemorrhage and white matter injury.^{73,74} Multiple administration of dexamethasone before or after birth was associated with a reduction in cortical involution and in the cerebral surface area,^{75,76} though the clinical significance of these findings is not known. Normal physical and mental development of children and young adults is reported, nonetheless, after prenatal exposure to steroids.^{77–80} Similarly, no negative effects on neuro-psychological development and on intelligence were found in a cohort of preschool- and school-age children exposed prenatally to prolonged treatment with dexamethasone.⁸¹

Maternal Effects

Dexamethasone given at doses greater than 1.5 mg per day suppresses the hypothalamic-pituitary-adrenal function. Gradual reduction in dosing is required if given for more than 2 weeks. Side-effects to systemic glucocorticoids include an increased susceptibility to infections; changes in mood such as irritability, euphoria, mania, depression and anxiety; weight gain; fluid retention; arterial hypertension; glucose intolerance; insomnia; hirsutism; striae; impaired wound-healing; stomach irritation; and headache. In Toronto, we have now consecutively treated 30 pregnancies with immune-mediated fetal complete heart block. Adverse effects attributed to the use of steroids included the development of severe oligohydramnios in five pregnancies, requiring premature delivery in three cases, maternal hypertension in two cases, discontinuing the drug in one case, insulin-dependent diabetes in another case, and three

women complaining about insomnia or mood changes, which resolved after reducing the dose. We now monitor carefully the volume of amniotic fluid throughout gestation, and taper the dose to 2 mg per day at around 30 weeks gestation to reduce the risk of severe oligohydramnios.

Beta-sympathomimetic Drugs

Beta₂-adrenergic receptor stimulation with short-acting terbutaline, ritodrine, and salbutamol has widely been used for tocolysis. Simultaneous β₁-actions may increase the fetal and maternal cardiac output by a change in heart rate and a decrease in systemic vascular resistance.^{82–84} These effects have been used to treat the fetus with a slow heart rate and/or reduced myocardial function. Indeed, fetuses with complete atrioventricular block often respond to transplacental β-stimulation with a small, but persistent increase of 5 to 10 beats per minute, without necessarily improving the chance of survival of a haemodynamically compromised fetus.^{52,60,67,85–89} If β-stimulation was used in combination with dexamethasone, five-sixths of fetuses with isolated complete atrioventricular block and with heart rates below 55 beats per minute survived to infancy.⁶⁰

Dosing, Pharmacokinetics, and Adverse Events

Oral salbutamol and terbutaline, administered at or close to the maximal recommended daily doses, are the predominantly used β-agonists. The drugs are rapidly absorbed from the gastrointestinal tract, and incompletely cross the placenta, providing ratios of about 1:2 for umbilical cord and maternal samples.^{90,91} While salbutamol and terbutaline are in general well-tolerated, mothers on maximal oral β-mimetic treatment regularly complain about mild tremor, palpitations and sweating.^{52,60} These symptoms become better tolerated or resolve after some time of therapy. More serious maternal adverse events, or intolerable symptoms that required a change in treatment, have not been reported, nor were they observed by us. Tocolytic therapy with parenteral β-sympathomimetic agents, nonetheless, may rarely be associated with maternal pulmonary oedema, myocardial ischaemia, cardiac arrhythmias, hypotension, hyperglycemia, ketoacidosis, and hypokalemia.^{92–94} Transient hypoglycemia has also been reported in newborn preterm infants after maternal treatment. Beta-agonists should be used cautiously, or not at all, in mothers with diabetes, hypertension, hyperthyroidism, and a history of seizures or tachyarrhythmias.

The outcome for fetuses with immune-mediated complete atrioventricular block, therefore, has significantly improved during the last decade, coinciding with a change in overall management of affected pregnancies that included the introduction of transplacental anti-inflammatory and β-sympathomimetic treatment. Based on the present knowledge on risks and benefits of treatment, there is no solid ground to deny the obvious improvement in survival to the fetus with newly diagnosed immune-mediated atrioventricular block. New strategies are evolving that aim at the prevention of fetal heart block. This includes echocardiographic diagnosis and pharmacological treatment closer to the onset of immune-mediated damage to the cardiac tissues.

CATHETER INTERVENTION FOR FETAL STRUCTURAL CARDIAC DISEASE

Owing to steady advances in ultrasonic imaging, congenital malformations of the heart can now accurately be diagnosed as early as the first trimester, and the progression of

disease followed during the course of pregnancy. Not unexpectedly, prenatal worsening of cardiac anomalies has been well documented in both individual reports and series. For example, valves may become more incompetent, stenotic, or atretic, potentially leading to secondary damage of the heart, lungs, brain and other organs. Impaired growth of ventricles and vessels may result in a functionally univentricular circulation. Valvar regurgitation has the potential to lead to congestive cardiac failure and fetal hydrops. On the other hand, timely intra-uterine intervention may lead to improved or normalised haemodynamics, thus reducing the likelihood of abnormal fetal development, circulatory failure, and intra-uterine death.

Fetal intervention was pioneered in 1991, when Maxwell and colleagues dilated a stenotic aortic valve.⁹⁵ The previous 12 patients diagnosed with this condition at their centre had not survived postnatal treatment, so the aim of the fetal intervention was simply to ensure survival. Following this initial report, valvoplasties were undertaken at several other institutions around the world. The results of this experience were disappointing, with aortic valvoplasty technically successful in only just over half the cases, and only 1 patient surviving over the long term.⁹⁶ In light of improving surgical results in children with hypoplastic left heart syndrome, and the discouraging results of prenatal intervention, procedures were abandoned for some time. The reasons for prenatal intervention, however, have changed since 1991. The goal nowadays is no longer simply to ensure fetal survival but, more ambitiously, to reduce morbidity, for example by promoting intra-uterine ventricular, valvar and vascular growth so as to avoid development of a functionally univentricular circulation, or by restoring normal cerebral perfusion to improve the neurological outcome. The achievements of these goals depend on an evidence-based selection of suitable candidates, on the level of expertise and cooperation of the team performing the intervention, and on the availability of adequate technical equipment. Only limited cardiac lesions have the potential to benefit from prenatal interventions, specifically critical aortic valvar stenosis, critical pulmonary valvar stenosis or atresia with an intact ventricular septum, and hypoplasia of the left heart in the setting of a closed or severely restrictive oval foramen.

CRITICAL AORTIC VALVAR STENOSIS

Aortic stenosis typically leads to increased left ventricular pressure and hypertrophy. If ventricular growth and function are maintained, the patient with severe aortic stenosis is usually a good candidate for postnatal balloon dilation. In a subset of fetuses, however, the left ventricle progressively fails to overcome the increase in afterload despite generating maximal systolic pressure. As a consequence, the left ventricle progressively dilates, its contractile and filling function worsens, and signs of endocardial fibroelastosis appear. Related to the impaired diastolic function, left atrial pressure rises, and left-to-right shunting becomes visible echocardiographically across the patent oval foramen. In some fetuses, dilation of the high-pressure left ventricular cavity may severely impair right ventricular diastolic and systolic function, and cause fetal hydrops.⁹⁷ If the left ventricle is unable to eject blood into the aorta, the upper body will be supplied by the right ventricle via the patent

Figure 12-3 Graph of left ventricular end-diastolic volume versus gestational age in fetuses with aortic stenosis. (Reproduced with permission from Simpson JM, Sharland GK: Natural history and outcome of aortic stenosis diagnosed prenatally. *Heart* 1997;77:205–210.)

arterial duct. At this stage, growth of the left ventricle and aortic arch slows down or ceases (Fig. 12-3).^{97–101} The typical finding at birth is a neonate with a left heart that is too small to sustain the systemic circulation, and which cannot be anatomically corrected. If the parents elect active postnatal care, this is usually done by step-wise palliative surgery involving the Norwood sequence of operations, and culminating in conversion to the Fontan circulation, or by cardiac transplantation. In a subset of fetuses, however, early relief of the obstructed aortic outflow by fetal intervention might restore left ventricular growth and function to an extent that would allow biventricular repair, rather than functionally univentricular palliation after birth. Prior to any intra-uterine intervention, nonetheless, it is important to pose three questions. First, are there evidence-based criteria to identify a suitable candidate for fetal valvoplasty? Second, can the procedure be effectively performed with minimal risks to the mother and fetus? Third, is a technically successful intervention likely to result in the desired outcome?

Reasons for Fetal Dilatation of the Aortic Valve

As discussed, the primary goal of the first fetal cardiac interventions was to improve the chance of survival for a group of children with a high institutional mortality rate. As hypoplastic left heart syndrome is now surgically manageable with more acceptable results, this motivation no longer holds true. The exception is the rare circumstance of a hydropic fetus with severe right ventricular compression by a dilated left ventricle. Decompression of the left ventricle will improve right ventricular filling and output, and might prevent almost certain intra-uterine death. In the remaining cases with critical aortic stenosis, the reason for intra-uterine intervention is to preserve a biventricular circulation after birth, with a normal quality and expectancy of life. Another argument for intra-uterine aortic valvoplasty relates to cerebral perfusion and development. Flow of blood to the brain of the fetus with severe left ventricular outflow obstruction is sustained by the right ventricle via the patent arterial duct. This results in a lower than usual oxygenated cerebral blood supply, and may also alter the pattern of cerebral perfusion. Pulsed wave Doppler assessment of the mid-cerebral arterial flow may show increased

end-diastolic velocities and lower pulsatility indexes, similar to the severely growth-restricted fetus with brain sparing.^{102,103} The finding is explained by an auto-regulatory lowering of the cerebro-vascular resistance to enhance cerebral perfusion, and has been correlated with an impaired neurological outcome.¹⁰⁴ Abnormal cerebral perfusion may account for the abnormal neurodevelopment and lower circumferences of the head found in many offspring with hypoplastic left heart syndrome.¹⁰⁵ Other disease-related long-term risks include thrombo-embolic events, protein-losing enteropathy, plastic bronchitis, arrhythmias, and early ventricular dysfunction (see Chapter 32).

With this morbidity in mind, prevention of a functionally univentricular postnatal circulation by means of a well-timed prenatal intervention inevitably becomes an ideal goal. If significant endocardial fibroelastosis of the left ventricle is already present at the time of diagnosis, however, diastolic function may remain abnormal despite a technically successful valvoplasty. Abnormal ventricular compliance due to the diffusely thickened endocardium may lead to left atrial and pulmonary arterial hypertension, with unfavourable consequences for the child subsequent to attempted construction of a biventricular circulation. Moreover, a borderline-sized left ventricle with a narrowed left ventricular outflow tract may require a Ross or a Ross-Konno operation, with the need for further surgery later in life. The situation becomes even more complex if the mitral valve is dysplastic, stenotic, and/or hypoplastic, and will need to be repaired or replaced, in particular if the child is still at a young age. Thus, at least for some cases with more complex left ventricular pathology, the question must arise whether a well-performed functionally univentricular palliation is not superior to a malfunctioning biventricular repair.

Selection of Patients

The ideal candidate for percutaneous fetal balloon valvoplasty is the mid-trimester fetus with isolated critical aortic valvar stenosis and an adequate sized, apex-forming left ventricle that will become hypoplastic unless the obstruction is successfully relieved. In a series of patients with prenatal diagnosis of this entity at the Boston Children's Hospital, such progression to hypoplastic left heart syndrome could

Figure 12-4 Typical appearance of a suitable candidate for fetal aortic valvoplasty. **A**, The dilated and poorly contracting left ventricle with endocardial brightness suggesting endocardial fibroelastosis. **B**, Retrograde flow in the transverse aortic arch. The fetus also had a monophasic left ventricular Doppler inflow pattern and left-to-right shunting across the patent oval foramen. LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle.

not be predicted by anatomical findings, but necessitated the inclusion of physiological parameters.¹⁰⁶ All cases with progressive left heart hypoplasia had a retrograde pattern of flow in the transverse aortic arch, while nine-tenths had left-to-right shunting across the oval foramen, monophasic mitral inflow, and significant left ventricular dysfunction on the initial fetal echocardiogram. In contrast, all fetuses with a preserved biventricular circulation after birth had normal antegrade flow in the transverse aortic arch, a biphasic mitral inflow pattern, and normal left ventricular systolic function (Fig. 12-4). Retrograde flow in the transverse aortic arch predicted neonatal hypoplastic left heart syndrome with complete sensitivity and specificity. This data supports the concept that fetal disturbances of flow contribute to the development of ventricular hypoplasia. The unsolved, yet critically important, question remains as to whether the dysfunctional left ventricle is capable of recovery after successful fetal intervention.

Technique of Fetal Aortic Valvoplasty

Fetal intracardiac interventions are the effort of a closely collaborating team that minimally includes an obstetrician with experience in ultrasonic guided fetal procedures, a fetal cardiologist, and an anaesthetist. The interventional procedure may be performed under general anaesthesia, where the fetus is anaesthetised via the mother, or using local anaesthesia, where narcotics and muscle relaxants are directly injected into the fetus. The interventional techniques have been described in detail by different authors.^{95,96,107} Under ultrasonic guidance a cannula and stylet needle are advanced through the maternal abdomen, the uterine wall, the amniotic cavity, the fetal chest, and into the left ventricle (Fig. 12-5). The success of valvoplasty critically depends on a suitable fetal position, and on high-quality transabdominal or transuterine fetal echocardiographic imaging. Care must be taken to insert the needle at an angle that is directly pointed towards the

left ventricular outflow tract. After removal of the stylet, a floppy guide-wire is advanced across the stenotic aortic valve into the ascending aorta and aortic arch. A standard coronary balloon catheter is then advanced over the wire to perform multiple dilations of the aortic valve. Inflations to ratios of balloon to valve of between 0.8 and 1.2 have been used. Following successful dilation, stylet and balloon are removed together in one step (Fig. 12-6).

After little success with their first five cases, the team from Boston Children's Hospital added the option of a laparotomy for those cases with an unfavourable fetal position, and/or poor transabdominal fetal ultrasonic imaging.¹⁰⁸ Such laparotomies, performed in two-thirds of cases, improved the rate of technical success from 20% to 83%. A considerable learning curve reduced the need for a laparotomy with increasing experience. We have used exclusively a transabdominal approach, and have achieved success in five of eight cases, improved to five of our most recent six cases, highlighting the importance of a critical number of patients to attain and maintain the necessary skills and expertise for successful interventions.

Several complications have been reported during and after fetal aortic valvoplasty. Fetal bradycardia at around 50 beats per minute lasting more than 1 minute occurs in almost half of fetuses once the left ventricle is punctured. This can be prevented or abolished by fetal injection of atropine or epinephrine adjusted to the estimated fetal weight. A small pericardial effusion is observed in most cases immediately after withdrawal of the cannula, which usually resolves within a few hours. The pericardium should be drained, however, if the effusion increases in size, or haemodynamic compromise is suspected. Thrombus may form in the left ventricle, especially if the procedure takes some time. Once a thrombus has formed, the echocardiographic visibility of the fetal heart becomes poor, and the chance of successfully performing the procedure is dramatically reduced. The thrombus usually resolves within 24 hours without specific treatment. When using larger ratios of balloon to

aortic valve, aortic regurgitation is likely to appear. Unlike the postnatal situation, even severe valvar insufficiency resolves within a few weeks. This suggests that remodeling of leaflets is possible prenatally. Whether aortic regurgitation promotes ventricular growth by increasing volume load, or further impairs left ventricular myocardial function due to a theoretical decrease in coronary arterial perfusion pressure, is unknown. Death of the fetus within 1 to 3 days after the procedure occurred in one-sixth of the procedures in the Boston experience, while this was the case with the first two of our eight patients treated in Linz. More recent unpublished data from Boston now indicates an early post-interventional rate of fetal death of approximately 10%.

Results and Outcomes

Technical success is defined by a successful positioning of the balloon catheter across the stenotic aortic valve, followed by one or several dilations resulting in a broader jet of ejection across the stenotic valve. After the initial disappointing experience, a technically successful procedure is nowadays possible in approximately four-fifths of cases if performed by experienced interventionists. The components of the left heart grow significantly better after a successful valvoplasty when compared to the fetus with an unsuccessful procedure, or with no attempt to intervene (Fig. 12-7). Unfortunately, technical success and improved left heart growth does not always produce a biventricular postnatal outcome. In the initial experience reported from Boston, biventricular repair was achieved in only 3 of 14 cases with technically successful fetal valvar dilation.¹⁰⁷ Their more recent report, including 26 fetuses, demonstrates several significant improvements in the fetal haemodynamics after successful valvoplasty.¹⁰⁹ This included re-establishment of antegrade flow in the transverse aortic arch, the change from an exclusive left-right to a bidirectional flow pattern across the oval foramen, improvement to biphasic left ventricular inflow, and an increase in the average left ventricular ejection fraction. Of five successful interventions in Linz, four patients went on to delivery, and all achieved biventricular repair, albeit including the need for Ross-Konno procedures

Figure 12-7 The change in dimensions of left heart structures in fetuses with a technically successful fetal aortic valvoplasty (blue bars) are compared to those after an unsuccessful or declined procedure (orange bars) (Reproduced with permission from Tworetzky W, Wilkins-Haug L, Jennings RW, et al: Balloon dilation of severe aortic stenosis in the fetus: Potential for prevention of hypoplastic left heart syndrome. Candidate selection, technique and results of successful intervention. *Circulation* 2005;110:2125–2131.)

in three, replacement of the mitral valve at 6 months in one, and redilation of the aortic valve in another.

Current data, therefore, suggests that an immediate biventricular repair after birth can be achieved in only about one-third of patients. In those fetuses born with components of the left heart that are too small despite a successful intra-uterine valvoplasty, larger components of the left heart, and antegrade aortic flow, may facilitate functionally univentricular palliative surgery, and reduce the risk of neuro-developmental impairment.

CRITICAL PULMONARY STENOSIS AND ATRESIA WITH AN INTACT VENTRICULAR SEPTUM

Pulmonary valvar stenosis or atresia with an intact ventricular septum presents with a variable spectrum of pathology, ranging from good-sized to variably small and dysfunctional right ventricles and tricuspid valves. Prenatal detection of this anomaly is feasible, and even anatomical details such as right ventriculo-coronary connections can be readily detected by high-resolution echocardiography.^{110,111} Progression of the severity of pulmonary stenosis has been observed during the course of pregnancy.^{112–114} If detected sufficiently early, up to four-fifths of those with pulmonary atresia with intact ventricular septum undergo termination, significantly reducing the incidence of this anomaly at birth in some countries.¹¹⁵ Spontaneous intra-uterine death also occurs in approximately one-twentieth, but most fetuses will survive to birth without problems.

Morbidity and mortality mainly depend on whether a biventricular, functionally univentricular, or the so-called one and a half ventricular repair can be achieved after birth (see Chapter 30). Postnatal treatment includes intravenous administration of prostaglandins to prevent closure of the arterial duct. Different interventional and surgical options are then used to open the obstructed pulmonary valve, and to decompress the right ventricle in the absence of a right ventricular-dependent coronary arterial circulation, and/or to place a systemic-to-pulmonary arterial shunt. This includes radio-frequency perforation and balloon dilation of the pulmonary valve, stenting of the arterial duct, placement of a modified Blalock-Taussig shunt or a homograft from the right ventricle to the pulmonary arteries, as well as enlargement of the right ventricular outlet tract with a patch. Despite significant improvements in postnatal management, mortality remains high,^{114,116–119} with only around two-thirds of cases, or less, proceeding to biventricular repair. There is evidence that, even in patients with an advantageous biventricular repair, right ventricular growth and biventricular function may be impaired, with unknown consequences for the long term.^{120–122}

Reasons for Fetal Pulmonary Valvoplasty

In the fetus with critical pulmonary valvar stenosis or atresia and an intact ventricular septum, with signs of imminent cardiac failure due to restrictive right-to left shunting across the oval foramen, fetal pulmonary valvoplasty is performed to ensure survival. As most fetuses will not develop restrictive atrial flow leading to cardiac failure, the primary intention of fetal intervention in most instances is to prevent

progressive hypoplasia of the right heart, thus promoting the potential for postnatal biventricular repair.

Selection of Patients

Prenatal prediction of whether or not a biventricular circulation will be achieved after birth is crucial for parental counselling, and for selection of those fetuses who may profit from fetal valvotomy to salvage the right heart. Uncertainty regarding the ultimate outcome may influence management of pregnancy, and may also lead to unnecessary fetal intervention. The question, therefore, is whether it is indeed possible accurately to predict the potential for right ventricular growth, and hence a biventricular outcome, in the fetus with pulmonary stenosis or atresia. The group from Boston studied whether measurements of tricuspid valvar size, and the respective z-scores, could be used in this fashion.¹²³ They found that biventricular repair was unlikely when the z score was -3 or worse, but always possible when better than -3 . Almost two-thirds of those with z scores worse than -3 also had right ventricular dependent coronary arterial circulations, compared to none with the more favorable scores. The z scores noted at mid- and late-gestation also correlated with those measured after birth. Groups from Toronto and Montreal have also sought to identify ultrasonic markers for biventricular versus non-biventricular surgical outcomes.¹¹¹ Poor right ventricular function, reversal of flow in the arterial duct, the degree of tricuspid valvar regurgitation, and the Doppler pattern of flow in the inferior caval vein did not discriminate. By assessing the ratio of tricuspid to mitral valvar diameters, using 0.7 as the cut-off, the ratio of the lengths of the ventricles, with 0.6 being the break point, duration of tricuspid valvar inflow of less than three-tenths of the cardiac cycle length, and the presence of right ventricular to coronary arterial communications, it proved possible to predict a functionally univentricular outcome with sensitivity of 100% and specificity of 75% if three out of these four parameters were observed.

A subset of fetuses with pulmonary atresia and intact ventricular septum present with severe tricuspid regurgitation

and a grossly enlarged right heart secondary to tricuspid valvar dysplasia or Ebstein's malformation. In this setting, pulmonary atresia may be functional as opposed to anatomic, as the right ventricle fails to generate enough force to eject the blood into the pulmonary vascular bed.¹²⁴ Dilation of the functionally closed pulmonary valve, therefore, would not improve the haemodynamic situation because the primary cause, right ventricular and tricuspid valvar dysfunction, would not be addressed. Measurement of the velocity of the jet of tricuspid regurgitation to estimate right ventricular pressure might help, nonetheless, to separate anatomic from functional pulmonary valvar occlusion.

Technique of Fetal Pulmonary Valvoplasty

The techniques used for dilation of the pulmonary valve are comparable to those used for the aortic valve. The procedure, however, is more technically challenging. The right ventricular cavity to be punctured is, in general, far smaller than the dilated left ventricle found in the setting of fetal aortic stenosis. Moreover, the optimal angle to advance the cannula from the right ventricular outflow tract across the pulmonary valve and into the pulmonary trunk is almost perpendicular to the fetal chest, and hence more difficult to achieve. The atretic pulmonary valve also needs to be perforated with a sharp needle to permit advancement of the guide-wire and balloon across the valve. This increases the risk for procedure-related complications (Fig. 12-8).¹²⁵

Results and Outcome

The first successful intra-uterine pulmonary valvuloplasty in a fetus with an atretic pulmonary valve was achieved in our centre at Linz.¹²⁶ The fetus had been thought to develop cardiac failure secondary to a large atrial septal aneurysm that protruded into the mitral valve and obstructed the left ventricular inflow. Following successful pulmonary valvar perforation and balloon dilation, the tricuspid regurgitation disappeared, and the right ventricular inflow improved from a monophasic to biphasic pattern (Fig. 12-9). In addition, signs of cardiac failure improved, and the right ventricle

and the pulmonary valve continued to grow with advancing gestation. Several weeks after the fetal intervention, the pulmonary valve had restenosed. The newborn infant underwent successful pulmonary valvar dilation, but also required construction of a modified Blalock-Taussig shunt. At 8 months of age, it proved possible to take down the shunt and create a biventricular circulation. Subsequently, we reported the combined experience of the Children's Heart Centre in Linz and the Royal Brompton Hospital in London.¹²⁷ We attempted six interventions in five fetuses with pulmonary atresia or critical pulmonary stenosis between 23 and 30 weeks of gestation. Of the procedures, four were technically successful, but pulmonary atresia reappeared in two cases. In one fetus with a large coronary arterial fistula, the fistula remained unchanged despite successful valvotomy with right ventricular decompression. Reasons for the two technical failures included placental bleeding related to an intervention across an anterior placenta, and poor visibility in an obese mother. Biventricular repair was achieved in two of the children, one child underwent a one-and-a-half ventricle repair, while two patients died in the neonatal period. To date, eight procedures have been undertaken at Boston Children's Hospital, as yet unreported. The first four were technically unsuccessful, and the neonates required construction postnatally of a functionally univentricular circulation. The more recent attempts have been technically successful, with three fetuses proceeding to postnatal biventricular repairs, and the other requiring a modified Blalock-Taussig shunt in addition to a patch across the right ventricular outflow tract.

Echocardiographic criteria to predict univentricular versus biventricular outcomes, therefore, are available, and can be used to select suitable candidates for fetal pulmonary valvoplasty. The interventions on the pulmonary

valve, however, are technically more challenging than those on the aortic valve. The benefit of the procedure in terms of improved postnatal outcomes is still to be established.

INTACT OR HIGHLY RESTRICTIVE ATRIAL SEPTUM ASSOCIATED WITH OBSTRUCTIVE ANOMALIES OF THE LEFT HEART

In the fetus with severe left ventricular inflow obstruction, unrestricted flow across the oval foramen is essential to ensure unobstructed pulmonary venous drainage from the left to the right atrium. If the left-to-right atrial shunt is restrictive, left atrial hypertension and pulmonary venous congestion develop, often with major consequences on the pulmonary vascular morphology and function.¹²⁸ Accordingly, children born with hypoplastic left heart syndrome and a restrictive or intact atrial septum have a substantial increase in morbidity and mortality, even when the obstruction is successfully relieved immediately after birth by an emergency atrial septostomy.¹²⁹

Reasons for Intra-uterine Atrial Septostomy

The poor outcome of infants with hypoplasia of the left heart and a highly restrictive or intact oval foramen was the primary reason to intervene on the atrial septum prior to delivery. The aim of the intervention is to facilitate left-to-right shunting, thus decompressing the left atrium and pulmonary venous system. In theory, at least, this should allow for a more normal pulmonary vascular development, with an improved postnatal outcome.

Selection of Patients

Whenever a fetus with an intact or severely restrictive atrial septum in the setting of severe mitral valve stenosis or atresia is identified, the option of prenatal atrial septostomy should be considered. On cross sectional echocardiography, the atrial septum will be seen to bulge into the right atrium, and will appear thickened and muscularised, while the pulmonary veins will be dilated. Colour and pulsed wave Doppler echocardiography should be used to examine the pattern of flow and velocities across the oval foramen and in the pulmonary veins. It is well-known that the fetus with hypoplastic left heart syndrome has a Doppler pattern of pulmonary venous flow that differs from the normal fetus, even in the absence of atrial septal restriction. If the pulmonary venous flow has minimal or no early diastolic forward movement, but shows significant reversal during atrial contraction, this will indicate severe restriction of intra-atrial flow (Fig. 12-10).^{130–132} Moreover, assessment of the severely restrictive atrial shunting by Doppler interrogation will show continuous left-to-right shunting at high velocity, suggesting a significant pressure gradient between the two atriums (Fig. 12-11).

Technique of Fetal Atrial Septostomy

The interventional technique is comparable to intra-uterine aortic or pulmonary valvoplasty. Using an ultrasonic guided percutaneous approach, either the right or the left atrial free wall is entered from the lateral chest wall, with

Figure 12-10 The pulmonic venous Doppler pattern of flow is seen during several cardiac cycles in a normal fetus and in a fetus (A) with hypoplastic left heart syndrome and unrestrictive atrial communication (B). Note the small amount of backward flow during atrial systole. C, Comparable findings in a fetus with hypoplastic left heart syndrome and an intact atrial septum: There is complete absence of early diastolic flow and increased flow reversal during atrial systole. A, late diastolic flow at the time of atrial contraction; D, early diastolic flow; S, systolic flow.

the cannula pointing perpendicularly to the atrial septum. A sharp needle is advanced via the cannula to perforate the thickened septum. A guide-wire is then advanced across the cannula into a pulmonary vein, followed by placement of a coronary arterial balloon catheter across the atrial septum. The balloon is then inflated to its maximal diameter (Fig. 12-12). The dilation can be repeated until adequate left-to-right atrial shunting is achieved. Larger communications, nonetheless, are usually not obtained by balloon dilation. Permanent decompression of the left atrium, therefore, may not be obtained. An alternative approach that may result in larger and more persistently patent communications is to implant a coronary arterial stent within the created atrial communication. This has successfully been achieved in one fetus by the group in Boston, albeit not yet described in the literature. It is also possible to use a Nd:YAG laser to fulgurate the atrial septal tissue rather than employing the needle, wire, and balloon.¹³³

Results and Outcome

The current experience with fetal atrial septostomy is very limited, effectively representing the experience obtained in Boston.¹³⁴ Interventions were attempted on seven fetuses between 26 and 34 weeks of gestation, of which six were technically successful. There were no maternal

complications. Of the fetuses, one died prior to birth, and the remaining cases were live born, albeit that all died in the neonatal period. The latest unpublished experience from Boston has extended to 18 fetal procedures, with technical success in more than nine-tenths, 17 of the fetuses being live born children, one dying prior to surgical intervention, and more than half successfully surviving postnatal surgical intervention.

Ultrasonically guided fetal atrial septostomy, therefore, is technically feasible, and can be achieved with a low risk of fetal death. Whether the procedure ensures permanent left atrial decompression, with reversal of pulmonary vascular abnormalities, and with improved postnatal outcome, remains to be established.

SUMMARY

Nowadays, a team of experienced clinicians can perform successful fetal intracardiac interventions with low risks to the mother and fetus. Identification of suitable candidates for interventions has improved in recent years. New modalities to assess myocardial function, such as tissue Doppler imaging, can provide additional information on the optimal timing of procedures, and the prediction of myocardial recovery. While technical rates of success have improved with more clinical experience, the development of more appropriate interventional tools would help further to increase the safety and efficiency of the procedures. The quality of the images obtained should not need to be improved by means of laparotomy, but rather by an improvement in ultrasonic resolution, and perhaps by adding real-time three-dimensional or transoesophageal fetal echocardiography.¹³⁵ Little is currently known about fetal resuscitation, and the application, safety, and efficacy of currently used drugs and potentially useful medication. At this stage, fetal cardiac interventions are not the standard of care, but tentative undertakings with potential pitfalls. As stated by Kleinman,¹³⁶ 'The paediatric community as a group is entering a field with complex and unique legal and ethical underpinnings that have been formulated during a period of more than 35 years. Unless it takes note of the experiences of our colleagues in maternal fetal medicine and paediatric surgery in the field of fetal intervention, it is likely that we and our patients will be doomed to revisit the errors of judgement that were made in well-intentioned efforts to treat fetal conditions such as diaphragmatic hernia, obstructive uropathy and hydrocephaly'. Only then will the future be bright for thoughtful applications of new techniques in fetuses with congenitally malformed hearts.¹³⁷

ACKNOWLEDGEMENT

We are indebted to Dr Wayne Tworetzky, of Boston Children's Hospital, for sharing with us the extensive, but as yet unpublished, experience of himself and his colleagues with the various lesions currently amenable to fetal intervention.

Infants born with hypoplastic left heart syndrome and an intact or highly restrictive atrial septum face a high postnatal mortality related to chronic pulmonary vascular disease. In this report, the group from Boston Children's Hospital demonstrated that left atrial decompression by prenatal catheter intervention is technically feasible with low risks, but were unable to find any positive clinical benefit on outcome.

Surgical Techniques

KIMBERLY L. GANDY, GEORGE M. HOFFMAN,
PATRICK VANDERWAL, and JAMES S. TWEDDELL

The conduct of an operation for palliation or repair of the congenitally malformed heart is ideally the culmination of a thorough preoperative evaluation, the careful formulation of an operative plan after interpretation of all data and the execution of this plan by a well-coordinated team. In this chapter, we review some of the issues that are common to all surgical procedures performed in patients with congenitally malformed hearts. We will describe the incisions that are used in the approach to the heart, the materials that are used to perform the necessary surgical manipulations and the strategies for intraoperative support.

SURGICAL APPROACHES TO THE HEART

There are a variety of incisions that are used in cardiac surgery. Until most recently, the majority of paediatric cardiac surgery was performed through two incisions, namely the median sternotomy and the left posterolateral thoracotomy. Over the last decade, minimally invasive strategies have resulted in the use of a variety of other incisions.

The Sternotomy

The most commonly used incision continues to be the median sternotomy (Fig. 13-1), in which the sternum is divided along its length from top to bottom. Originally

described in 1897, this incision came into widespread use after the advent of coronary artery bypass grafting in the 1960s. The overlying skin and subcutaneous tissues are divided with a combination of the knife and electrocautery, and the sternum is divided with a reciprocating saw (Fig. 13-2). In neonates and young infants, scissors can be used to divide the bone. The reciprocating saw is used when opening the sternum for the first time. The blade has vertical movement through a short distance, and a protective shoe covers the tip of the blade. The shoe glides underneath the sternum, and prevents injury to the underlying cardiac structures. At the completion of the procedure, the sternum is closed with stainless steel wire, bands, or sometimes, in small children, heavy suture material. The incision provides excellent exposure, and is preferred for most intracardiac procedures. In addition to opening the sternum itself, the incision is extended for a short distance into the upper abdomen, separating the rectus muscle in the midline. Because there is minimal interruption of muscle, and because the sternum is solidly reconstructed at the end of the procedure, the incision is less painful than other commonly used incisions, such as the thoracotomy. There is minimal respiratory compromise. Early extubation, effective coughing and deep breathing are easily achieved with this incision. Long-term functional results are excellent, and lung function is minimally perturbed. This is in

Figure 13-1 The median sternotomy. **A**, The skin, subcutaneous tissue, and presternal fascia are divided with a combination of the knife and electrocautery. The sternum is divided longitudinally with a saw. **B**, The incision is extended for a short distance into the upper abdomen, dividing the rectus abdominus muscle in the midline.

Figure 13-2 **A**, In primary sternotomies, the sternum is usually divided with a reciprocating saw. **B**, In redo sternotomies, the sternum is divided with an oscillating saw. There are a variety of sizes and shapes of blades that can be adapted for use with the oscillating saw.

contrast to the situation found after thoracotomies, where a degree of restrictive lung physiology is predictable.¹

When it is necessary for a patient to undergo a cardiac operation through an operative field that has been previously explored, the mortality and morbidity of the operation are increased.² Over the last several decades, however, the morbidity and mortality of reoperative surgery in the adult have significantly decreased.^{3,4} There has probably been a similar decrease in mortality of reoperative surgery in children. Resternotomy requires preparation. Careful preoperative assessment is necessary to determine if the patient is at increased risk for resternotomy haemorrhage. Axial imaging studies such as computerised tomographic scanning, and magnetic resonance imaging, can be examined to determine the relationship of structures such as the atrium, right ventricular outflow tract, and aorta to the sternum. The position of the aorta and calcified conduits can also be identified on angiography.

Preparation for emergent volume support, and identification of alternative sites of access for cardiopulmonary support, are essential. Blood should be immediately available at the time of resternotomy. In adults and older children, the femoral vessels are frequently used for access. In older patients who have had multiple previous cardiac catheterisations and cardiac surgical procedures, ultrasonic interrogation of the femoral vessels should be considered to verify patency. The brachiocephalic artery, accessed through the sternal notch, and the axillary vessels, provide alternative sites for emergency access. In infants, the common carotid and internal jugular veins may be used for emergent cardiopulmonary bypass. Preparation should also be made for external cardioversion should the patient develop an arrhythmia before direct access to the heart is obtained. Resternotomy is accomplished using an oscillating saw (see Fig. 13-2). This device has horizontal blade translating through a short distance that limits, but by no means eliminates, the risk of injury to underlying vascular structures. At the completion of a procedure, preparation for resternotomy should be made in any patient in whom resternotomy is likely. A sheet of polytetrafluoroethylene can be placed over the heart at the time of closure in a child in whom subsequent reoperation is anticipated.

Infection of the sternal wound, and mediastinitis, are rare complications in children, but do occur. For the most part these complications are more easily managed than in older patients.⁵ In particular, osteomyelitis of the sternum is exceedingly rare,⁶ and sternal resection, a common necessity in adults with an infected sternal wound, is virtually

never required in children. In children, re-exploration, debridement, irrigation, and immediate closure over drains has been successful.⁵ A variety of techniques have been used to address more significant infections including the use of vacuum dressings, omental flaps,⁷ and flaps of the rectus abdominus muscle.⁸ These techniques enhance drainage and neovascularisation, improving control of infection, and enhancing eventual closure. The approach to the sternum considered at high risk for dehiscence is a subject unto itself. Though this has not been an area of significant concern in paediatric cardiac surgery, as our patient population ages, it may soon become a more important consideration. The time is nearing when up to half of those undergoing surgery for congenital cardiac disease may be adults. A significant portion of these procedures will necessarily be performed through a resternotomy. When the patient is obese or diabetic or has undergone previous chest irradiation, this sternum can be considered at increased risk for dehiscence. Many of these patients will have undergone multiple previous sternotomies. As a result, blood supply to the sternum may be significantly reduced. Indeed, a large portion of these patients may have lost both internal mammary arteries during previous explorations. As such, additional measures may be taken with sternal closure. Double sternal wires, steel bands⁹ and sternal plates,¹⁰⁻¹⁴ which reduce movement and distribute stresses in the wound over larger areas, are strategies used to close the sternum at high risk of dehiscence.

As outcomes have improved after cardiothoracic surgery, interest in improving the cosmesis of incisions has emerged. The longitudinal skin incisions have been shortened significantly in some cases, even when the sternum is divided fully along its length. Another effort has involved abandoning the longitudinal skin incision altogether, in favor of a submammary or transverse skin incision (Fig. 13-3A).^{15,16} The incision has not been widely adopted secondary to fear of wound complications and compromised exposure, but some have reported excellent results with this incision, and very low rates of complication.¹⁷⁻²⁰ It is of note that the majority of the sensory supply to the chest wall enters laterally (Fig. 13-3B). If the submammary incision is appropriately performed, sensory supply to the breast should be uninterrupted.¹⁹ It is also important that this incision is made well below the mammary tissue. Significant compromise to development of the breasts has resulted when the incision has been made too high. In an older individual who has completed mammary development, the most inferior extent of the breast is more clearly delineated. In younger children, this line is not as clear. The future site of the mammary fold can be identified in an infant or young child by placing a hand on the anterior chest wall above the nipple and gently pushing caudad. A fold will be evident that will correspond reasonably well to the future mammary crease. In general, if the incision if made in a transverse fashion at the level of the xyphoid process, a nice cosmetic result will be possible, with preservation of developing mammary tissue.

The Thoracotomy

Thoracotomy incisions are commonly used for ligation of the patent arterial duct, repair of aortic coarctation, placement of a pulmonary artery band and construction of a systemic-to-pulmonary arterial shunt. A posterolateral

Figure 13-3 The submammary skin incision for median sternotomy. The skin and subcutaneous tissues (A) are divided with a combination of the knife and electrocautery (solid black line). The sternum is divided longitudinally, as it is in the standard median sternotomy (dashed line). The area is innervated (B) by nerves entering laterally.

thoracotomy is shown in [Figure 13-4](#). The skin incision is made in a curvilinear fashion along the path of the ribs ([Fig. 13-4A](#)). In most instances, the latissimus dorsi muscle is divided ([Fig. 13-4B](#)), but the serratus anterior is spared ([Fig. 13-4C](#)). The intercostal muscles are divided between the ribs to be spread. At times, even the latissimus can be spared, the approach to the thoracic cavity being made through a small space between these muscles, the so-called triangle of auscultation. In cases where greater exposure is necessary, especially in older patients, it may be necessary to harvest a rib to obtain ideal exposure. The skin incision can be limited compared to the length of the incision within the thoracic cavity. This incision is performed through a variety of intercostal spaces, depending on the level for which exposure is desired. The arterial duct and aortic arch are typically approached through the third or fourth intercostal space. Exposure for excision of pulmonary pathology typically involves an incision in the fourth or fifth intercostal space. Exposure for treatment of oesophageal pathology can be made through the left fifth through eighth intercostal spaces, or the right fourth or fifth intercostal spaces. Exposure to the diaphragm is usually through the seventh intercostal space.

The transverse thoracosternotomy incision is used when there is need for extensive thoracic exposure ([Fig. 13-5](#)). In this incision, both thoracic cavities are entered through bilateral anterolateral thoracotomies that are connected across the midline by a transverse sternotomy. This

incision gives excellent exposure to all of the mediastinal structures anteriorly. It is most commonly used for bilateral sequential lung transplantation, but has also been used for unifocalisation of aortopulmonary collateral arteries. The skin incision can be made as indicated in the figure to preserve development of the breasts. This incision is sometimes complicated by sternal malunion, characterised by a malaligned sternal union or sternal nonunion. Some have abandoned this incision for this reason, and prefer to approach the chest through bilateral anterolateral thoracotomies without dividing the sternum.²¹ The use of alternative wiring techniques or alternative materials such as cables for sternal approximation have been reported and may reduce the incidence of complications with the transverse sternotomy.²²⁻²⁴

The anterolateral thoracotomy is shown in [Figure 13-6](#). The right anterolateral thoracotomy has been used for repair of a variety of congenital cardiac malformations, with good results.²⁵⁻³⁰ The anterolateral thoracotomy can be placed in the mammary crease and has been used as an alternate, more cosmetically appealing approach for simple intracardiac operations such as closure of atrial septal defects.³¹ There have been isolated reports, however, of compromised or asymmetric development of the breast with this incision,^{32,33} and of increased pain.³⁴ The left anterolateral thoracotomy is often used on the haemodynamically unstable victim of thoracic trauma with suspected damage to the thoracic structures. If sufficient access is not possible

Figure 13-4 The posterolateral thoracotomy. A, The skin and subcutaneous tissues are divided with a combination of the knife and electrocautery along the indicated line. In the most common iteration used today, the latissimus muscle is divided and the serratus anterior is spared. The intercostal muscles in the intercostal space of entry are also divided. B, The undivided latissimus dorsi. C, The divided muscle with the spared serratus anterior.

Figure 13-5 The transverse thoracosternotomy. The skin and subcutaneous tissues are divided with a combination of the knife and electrocautery along the solid line as indicated. A subcutaneous flap beneath the breast tissue is developed until the fourth or fifth intercostal space is reached. The intercostals are then divided at the desired interspace (*dashed line*). The internal mammary arteries are identified and ligated. The sternum is then divided transversely at the interspace in which the thoracic cavities were entered.

with this incision, it can be extended across the midline for further access to cardiac structures.

Minimally Invasive Approaches

In continued attempts to improve the cosmetic results after surgery, a variety of minimally invasive techniques have emerged. Originally applied to adults, they are now frequently applied to children. Among these techniques are partial upper and lower sternotomy, video assisted

thoracoscopic surgery, the mini-thoracotomy, the subxiphoid approach to the heart and robotic techniques.³⁵⁻³⁸ Use of these techniques is controversial. Opponents cite the potential for compromised exposure, and the accompanying increased risk of the procedure. Proponents cite the psychosocial benefits of smaller incisions. The potential for limited exposure must be balanced against the complexity of the case, and the likelihood of future reoperation. Partial sternotomies can consist of a partial superior sternotomy or a partial inferior sternotomy. The partial upper sternotomy has been used for such complex procedures as the arterial switch operation.³⁹ The inferior partial sternotomy has been commonly used for many years for procedures such as placement of epicardial pacemaker leads, where access to the anterior portion of the heart or atrium is needed. Atrial septal defects have been repaired through this incision.⁴⁰ More recently, a broader range of cardiac operations have been performed through this incision including closure of ventricular septal defects, repair of tetralogy of Fallot and atrioventricular septal defect with common junction, and procedures on the mitral valve.³⁹⁻⁴⁴ In small children with more pliable sternums, a similar variety of procedures has been accomplished through a subxiphoid incision.⁴⁰

Video assisted thoracic surgery has become a mainstay of general thoracic surgery during the last decade. In this type of procedure, one large incision is replaced by two to four smaller incisions (Fig. 13-7). A thoracoscope is placed through one incision. Others ports are used to place stapling devices, thoracoscopic scissors or instruments for dissection and retraction. The technique has been used for ligation of the arterial duct, closure of interatrial communications and division of vascular rings.⁴⁵⁻⁴⁹ In some series, pain and postoperative stay are significantly reduced.⁵⁰⁻⁵⁴ The relative advantages of different minimal-access procedures will vary depending on the strengths and weaknesses of individual institutions.^{40,52}

There are no long-term data on the effectiveness and complications associated with many of these techniques.

Figure 13-6 The anterolateral thoracotomy. The skin and subcutaneous tissues are divided with a combination of the knife and electrocautery along the line indicated. In some individuals, it is necessary to develop a flap beneath the subcutaneous tissue in order to reach the desired intercostal space. The pectoralis major and the intercostal muscles in the desired space of entry are then divided. In some individuals, the skin incision can be made more laterally, avoiding division of the pectoralis major.

Figure 13-7 Incisions for video assisted thoracoscopic surgery. Most procedures are attempted with isolation of the lung, in which it is possible selectively to deflate the lung in the operative thoracic cavity. Two to four small incisions are made as indicated depending on the procedure to be attempted. The intercostal muscles are divided in the rib space of entry with electrocautery. (Adapted from Soukiasian HJ, Fontana GP: Surgeons should provide minimally invasive approaches for the treatment of congenital heart disease. *Semin Thorac Cardiovasc Surg Pediatr Card Surg Annu* 2005:185–192.)

Opponents argue that the burden of proof rests with the proponents of the newer techniques before such techniques are adopted on a widespread basis.⁵⁵ Proponents argue that the technology is quickly improving, and that there are multiple potential benefits for children, such as shortened length of stay in hospital, earlier resumption of physical activity, reduction of postoperative pain, improved respiratory function and the reduction in the long-term morbidity associated with sternotomies and thoracotomies.⁵⁶

Open Sternum

After completion of a long, complex procedure, there may be significant accumulation of extravascular fluid in the heart, lungs, chest wall and even the peritoneal cavity. Reapproximation of the sternum can result in a significant reduction in cardiac output due to compression of the heart by adjacent structures, combined with the diastolic dysfunction that is the result of myocardial oedema. This acute restrictive physiology is similar to that seen with tamponade, and has been termed pseudotamponade physiology.⁵⁷ Because a period of decreased cardiac output is predictable following complex procedures, even the patient with initially acceptable haemodynamics may display pseudotamponade physiology within the first 12 hours following termination of cardiopulmonary bypass. Delayed sternal closure has been used commonly as a means of avoiding or managing low cardiac output syndrome in neonates and small infants undergoing complex procedures. Other indications for delayed sternal closure include ongoing bleeding that cannot be easily controlled. Occasionally, the sternal edges may be stented open to increase available space. Indications for an open sternum strategy and timing of closure vary greatly. For some, all patients undergoing the first stage of palliation for hypoplastic left heart syndrome undergo delayed sternal closure.^{58,59} For others, the strategy is applied on an individual basis.⁶⁰ Closure is undertaken when haemostasis has been achieved and the patient has diuresed and been weaned from the majority of inotropic support. Some have advocated waiting until the patient has diuresed to the preoperative weight.⁵⁸ While the sternum is open, the mediastinum is covered with either Gore-Tex or a silicone

sheet. This can be secured with adhesive, saving the skin edges from the injury of sutures.

MATERIALS

The job of the congenital cardiac surgeon often requires reconstruction of non-existent structures. The materials available for this task include biomaterials, synthetic materials, and combinations thereof.

Sutures

To date, sutures are necessary for any surgical task. Materials are usually classified as absorbable or nonabsorbable, and as monofilament or polyfilament. The choice of sutures depends on the specific application and stresses expected on the suture line or anastomosis. Vascular anastomoses are constructed most commonly with monofilament suture. The suture glides through the tissue easily, and this results in minimal damage to the tissue and improved haemostasis. For tasks such as fascial closure, absorbable braided sutures are commonly used, because they have a lower likelihood of tearing through tissue, and will be reabsorbed, minimising the risk of infection.

Absorbable sutures persist in the body for a limited period of time. Among the earliest absorbable sutures is gut, created from the intestines of cows or sheep. Used less commonly than in the past, the suture may be used untreated, or after treatment with chromium salts, a process which is thought to increase durability. More modern absorbable sutures include polygalactic acid (Vicryl, Johnson and Johnson, New Brunswick, NJ), and polyglycolic acid (Dexon, Tyco Healthcare, Gosport, Hampshire, UK). These polyfilament braided sutures are absorbed within 60 to 90 days. They are commonly used for closure of fascia, subcutaneous tissue and skin. Absorbable sutures are also available as monofilament. Polyglyconate (Maxon, Tyco Healthcare, Gosport, Hampshire, UK), and poliglecaprone (Monocryl, Johnson and Johnson, New Brunswick, NJ), have excellent strength when compared with other absorbable sutures, and are frequently used to close the skin. In addition to use in closing wounds, they have been used for vascular anastomoses. Polydioxanone (PDS, Johnson and Johnson, New Brunswick, NJ) is a monofilament suture that has a long duration

of absorbability, and high tensile strength, with the additional advantage of maintaining its integrity in the face of infection. It appears to induce less fibrosis than polygalactic acid. As a result, it is commonly used for surgery of the airway.

Among nonabsorbable sutures, one of the oldest is silk. It is considered nonabsorbable and polyfilament, though it is ultimately degraded. Although in the past silk was used for vascular anastomoses, today it is used for retraction or to ligate small vessels. Braided polyester sutures with Teflon coating (Tevdek, Tycron) have minimal memory, hold knots well, and are used frequently to secure patches used to close ventricular septal defects, or to secure prosthetic valves. Polypropylene (Prolene) is a monofilament suture that may last from 2 to 6 years. Its long durability, easy maneuverability, and tendency to glide easily through tissue, make it the suture of choice for cardiac reconstruction and vascular anastomoses. The Gore-Tex suture, made of polytetrafluoroethylene, is a monofilament nonabsorbable suture also used for vascular anastomoses. The suture is frequently used with Gore-Tex grafts to improve haemostasis of the suture line.

Patch Material and Valveless Conduits

One of the easiest materials to use is fresh autologous pericardium. The material is easily harvested at the time of a primary operation, though it is less easily harvested during reoperation. The material is pliable, sterile, and has no likelihood of inciting an immunological reaction. Some prefer for the pericardium to have firmer texture to increase ease of handling, in which case it is fixed in glutaraldehyde. Glutaraldehyde fixation results in cross-linking of collagen, making the pericardium stiffer. Such fixation may reduce aneurysmal formation when pericardium is used for vascular reconstruction.⁶¹ When native pericardium is not available, glutaraldehyde-treated bovine pericardium can be used. Though this tissue is readily available, and has minimal to no risk of transmission of disease, it has been known to stimulate an immune reaction, and undergo significant calcification.

Homograft aortas or pulmonary arteries, in other words cadaveric tissues, can also be used for vascular reconstruction. Such material is commonly used during reconstruction of the pulmonary arterial tree and confluence, or to relieve isolated pulmonary stenoses. They are also commonly used for reconstruction of the aortic arch in the neonate.^{58,62} The material is haemostatic, and easy to handle. It is, however, expensive, and it requires time for thawing, carries a risk of calcification, and comes in varying thicknesses that are often difficult to predict. In addition, homograft material can incite an immune response resulting in a nonspecific increase in anti-human lymphocyte antibodies, potentially complicating future transplantation.⁶³

Dacron, a synthetic polyester material, has been a mainstay in vascular reconstruction since its introduction in the 1950s. It is used in its tubular form to reconstruct vascular segments. It can also be used as a patch, and is commonly used for closure of ventricular septal defects. The Dacron material can incite a fibrous reaction. This is an advantage for closure of ventricular septal defects, in that such fibrous ingrowth may allow closure of the tiny residual defects at the edges of the patch. Fibrous ingrowth is even further enhanced when the Dacron is covered with velour.⁶⁴ Caution, however, should be used when Dacron is placed close

to an arterial valve, as fibrous ingrowth can impair motion of the valvar leaflets.

When used as a conduit, the porosity of Dacron poses a problem for haemostasis. In order to improve haemostasis, grafts can be pre-clotted by soaking them in either autologous blood or albumin, and then heating the grafts in an autoclave. In order to make the grafts easier to use, sealants have been developed and applied to the grafts. One example is the Hemashield Dacron graft (Medox Medical, Newark, NJ), in which formaldehyde cross-linked collagen is used to decrease porosity.

Polytetrafluoroethylene, with the trade name Teflon, and produced by the DuPont Corporation, Wilmington, Delaware, can be expanded or stretched such that it carries a pore size of 20 to 30 μm , a size that has been determined to be the optimal pore size for healing.^{65,66} The result is expanded polytetrafluoroethylene, commonly known as Gore-Tex (W.L. Gore and Associates, Flagstaff, AZ). It is used extensively for systemic to pulmonary artery shunts and for arterial reconstruction. Gore-Tex is thrombogenic, and a pseudointimal layer will develop over time that is the result of a combination of thrombus and cellular ingrowth.⁶⁷⁻⁷¹ This pseudointimal layer will decrease the caliber of small grafts, and can result in critical reduction of flow. Aspirin has been shown to improve patency of small caliber Gore-Tex grafts.⁷²

Valves and Valved Conduits

Decisions concerning valvar replacement in children are complicated because of the need to accommodate growth, the desire to avoid anticoagulation and the need for durability. Options in children can be divided into four broad categories: mechanical valves, xenobioprosthetic valves, homograft valves and autograft valves.

Mechanical Valves

Significant progress has been made with mechanical valves since the introduction of the first mechanical valve in 1952. Currently manufactured mechanical valves have either a single tilting disc, such as the Medtronic Hall Valve, or a bileaflet design, such as the St. Jude (St. Jude Medical, St. Paul, MN), Carbomedics (Austin, TX), ATS (ATS Medical, Minneapolis, MN), or On-X Valves (Medical Carbon Research, Austin, TX) (Fig. 13-8A). Structural failure of prosthetic valves is currently rarely reported. To date, all mechanical valves are thrombogenic, and necessitate anticoagulation. As a result, patients with mechanical valves are at risk for thromboembolic and bleeding complications. The risk of such complications is present, even in patients with optimally managed anticoagulation, and is influenced by factors specific to the patient, along with the position of the valve.

In adults, the incidence of thromboembolic complications among patients with a mechanical valve in the aortic position varies between 1.4 to 2.7 per patient per year, and bleeding complications between 0.7 and 2.3 per patient per year.⁷³ The risk of these complications with mechanical valves in the aortic position in children is less well known. In one report, the freedom from thromboembolic complications after 20 years was 93%.⁷⁴ Another series reported no episodes of thromboembolic complications, and only one incident of anticoagulation-related haemorrhage at a mean follow-up of 12 ± 6 years.⁷⁵ Although these two reports suggest that replacement of the aortic valve with mechanical

Figure 13-8 A, A typical bileaflet mechanical valve. Such valves are at risk for thromboembolic complications and anticoagulation is necessary. B, Adherent thrombus in an explanted valve. (Reproduced with permission from St. Jude Medical, Inc., St. Paul, Minnesota.)

prostheses in children has a low risk of anticoagulation-related complications, they summarise only relatively small experiences from single centres. The true risk probably falls between these reports and the larger adult experience.

The risk of complications related to anticoagulation is greatest for mechanical valves placed in atrioventricular position in the systemic circulation. Three separate reports summarising individual institutional experiences in children totaling 115 patients reported 10-year freedom from thromboembolic complications above 92%, and the risk of complications related to bleeding at between 76% and 97%.⁷⁶⁻⁷⁸ The true incidence of thromboembolic complications in children undergoing replacement of the mitral valve with a mechanical prosthesis is probably underestimated by those reporting from single centres. A multi-centre study found that 4 of 102 survivors of such replacement required re-replacement for thrombosis at a mean follow-up of 6.0 years.⁷⁹ Prospective studies of adults, with combined enrollment of over 1000 patients, showed that bileaflet mechanical valves in the mitral position were associated with an incidence of both thromboembolic events and complications due to bleeding at a frequency between 1% and 3% per patient per year.^{80,81} Freedom from thromboembolic complications after 10 years was 85.5%, and freedom from bleeding was 81.7%.⁸⁰

The most widely used prosthetic valve of the last decade is the St. Jude valve (Fig. 13-8B). It is a low profile, bileaflet valve constructed of pyrolytic carbon. In its most recent iteration, it has a rotatable valvar mechanism. Competing bileaflet designs include the ATS, On-X, and Carbomedics

valves. There has been considerable interest of late in the potential of utilising the On-X valve with aspirin as the only anti-thrombotic agent. The manufacturer claims that the lack of silicon coating on the carbon used to construct the valve makes it less thrombogenic. Controlled trials are underway to evaluate the risk of thromboembolic complications using only an antiplatelet strategy with the On-X valve.

Another major problem with mechanical valves when used in children is the limited availability of small sizes. Modifications of the sewing ring of the 19-mm Carbomedics and the 19-mm St. Jude valve have resulted in prosthetic valves that can accommodate a native annulus between 16 and 18 mm. Oftentimes, there is insufficient orifice for placement of even the smallest valve designed. Surgical techniques of annular enlargement, such as the anterior enlargement of Konno,⁸² or the posterior enlargement of Nicks⁸³ or Manouagian^{84,85} are used when the diameter of the native aortic root does not permit placement of a valve sufficiently large to meet the haemodynamic needs of the patient. In the mitral position, the anatomy does not lend itself as well to annular expansion. Other techniques must be utilised. Valves can be placed in the supra-annular position, or at angles, techniques that can permit placement of modestly larger prosthesis. Significant oversizing of mitral prostheses should be avoided, as this can result in subaortic obstruction.

Xenobioprosthetic Valves

Xenobioprosthetic valves include porcine aortic valves, either stented, as in the Hancock and Mosaic Valves (Medtronic, Minneapolis, MN) (Fig. 13-9), or nonstented,

Figure 13-9 A, A typical xenobioprosthetic stented porcine valve. B, Such valves, when inserted in children, undergo rapid calcification and degeneration. (A, Reproduced with permission from Edwards Lifesciences, Irvine, California.)

as in the Freestyle (Medtronic, Minneapolis, MN), Toronto SPV valve (St. Jude Medical, St. Paul, MN) and valves manufactured from bovine pericardium such as the Perimount valve (Edwards Life Science, Irvine, CA).^{86,87} Xenobioprosthetic material has been treated with glutaraldehyde in order to decrease immunogenicity and improve durability. In children, xenobioprosthetic valves undergo rapid calcific degeneration, limiting their use in the systemic circulation.⁸⁸ Recent efforts have been directed at newer techniques for preservation that limit this process of calcification.⁸⁹ Xenobioprosthetic valved conduits have been used for apicoaortic conduits for relief of obstruction of the left ventricular outflow tract, and in other rare circumstances where anticoagulation must be avoided, but in general xenobioprosthetic valves are rarely used in children in the systemic circulation.

Homograft Valves

Valved homograft material can also be used for valvar replacement and reconstruction (Fig. 13-10). The homograft is considered the conduit of choice for replacement of the aortic valve and aortic root in the face of endocarditis.⁹⁰⁻⁹⁵ Small homograft valved conduits are ideal for complex reconstruction in neonates and small infants, such as repair of common arterial trunk, and tetralogy of Fallot with pulmonary atresia. In North America, however, homografts in sizes suitable for neonates and small infants are becoming less and less available. The use of homografts to join the right ventricle to the pulmonary arteries is discussed more fully when considering selection of valves.

Pulmonary Autograft Valves

The pulmonary autograft used for replacement of the aortic valve (the Ross procedure) addresses some of the limitations in other options, and involves the harvest of the native pulmonary valve for replacement of the aortic valve.⁹⁶ The native outflow tract from the right ventricle is then reconstructed with another conduit, usually a homograft. The pulmonary autograft is frequently chosen for infants and small children. Although the autograft does allow for growth, late dilatation of the neo-aortic root with resultant aortic insufficiency has been identified in a subgroup of patients undergoing the Ross procedure. At least two mechanisms resulting in regurgitation appear to explain dysfunction of the autograft. Patients undergoing the Ross procedure for isolated aortic incompetence have

been shown to have an increased risk for development of incompetence, primarily due to dilation of the left ventriculo-aortic junction. Patients undergoing the Ross procedure for congenital aortic stenosis have an increased incidence of ascending aortic dilation, with dilation of the sinutubular junction that also results in aortic insufficiency. Efforts to limit development of autograft dilation and insufficiency include the use of annuloplasty sutures, and placement of the autograft within a Dacron tube graft.^{97,98} Both of these techniques limit the potential for growth, and are only suitable in older patients.

The autograft compares favourably to other options for replacing the aortic valve in children, but concern persists over long-term durability. In 150 patients under the age of 21 years, freedom from autograft failure of $84\% \pm 4\%$, and freedom from all valve-related complications of $72\% \pm 6\%$, were reported at 8 years.⁹⁹ Other series from Western Europe and North America, in which it is possible to differentiate the outcome for children, report freedom from reoperation of 83% to 88% at 5 to 6 years of follow-up.¹⁰⁰⁻¹⁰³ The long-term outlook of the pulmonary valve when used to replace the aortic valve remains unknown. Data from the Ross Procedure International Registry shows that the freedom from reintervention curve does not reach a plateau, and it seems likely that many of these patients will require additional procedures directed at the neo-aortic valve, as well as the predictable need for reintervention on the right ventricular outflow tract. Although it is generally acknowledged that the pulmonary homograft placed during the Ross procedure has greater longevity than that used for reconstruction of the right ventricular outflow tract for other forms of congenital cardiac disease, presumably due to the orthotopic position, normal pulmonary arteries and pulmonary vascular resistance, recent data indicate that replacement still will be necessary.^{104,105} Additional studies have indicated that even a mild, and apparently acceptable, gradient across the right ventricular outflow tract will increase importantly during exercise, and that exercise-induced arrhythmias are common following the Ross procedure.¹⁰⁶

Selection of Valves

No consensus has been reached on selection, but some generally accepted guidelines are presented. For use in the aortic position in neonates, infants and small children, the Ross procedure is commonly chosen, because it accommodates growth and anticoagulation is not required. Furthermore, the size of the autograft matches the size of the normal left ventricular outflow tract, and lesser degrees of enlargement of the aortic root are required compared to mechanical valves. Homografts can be used in the aortic position in infants and small children, either as a first choice, or if the pulmonary valve is deemed unsuitable for use in the aortic position. For older children, some continue to advocate the Ross procedure, although mechanical valves are also frequently used. Xenobioprosthetic valves within valved conduits have been used as conduits from the left ventricular apex to the aorta for relief of severe and complex obstruction in the left ventricular outflow tract.

Mechanical valves are generally used for the mitral (or systemic atrioventricular junction) position. Despite the need for anticoagulation, these valves have the necessary durability. Mortality after such replacement continues to

Figure 13-10 Aortic (A) and pulmonary (B) homografts. The valves are harvested along with a segment of the outflow tract and varying lengths of artery. (Reproduced with permission of Cryolite, Inc., Kennesaw, Georgia.)

be high in younger children. Results, however, seem to be improving, with one study showing reduction in operative mortality from 31% to 3.6% when comparing children receiving operations at the same institution before and after 1990.⁷⁶ A recent report showed an early mortality rate of 13% in children under 2 years of age undergoing replacement of the mitral valve,¹⁰⁷ a figure to be compared with a mortality rate as high as 52% in a report from 1990.¹⁰⁸ Xenobioprosthetic valves are rarely used in the mitral position due to the high rates of calcification and failure.^{109,110} Exceptions can be made, however, in extreme circumstances, such as haematological disorders or pregnancy, when the need to avoid anticoagulation is more definitive. There are advocates for the use of the pulmonary autograft in the mitral position, a procedure now known as the Ross II.¹¹¹ The autograft is placed within a Dacron tube graft. Although the viability may be good, and the need for anticoagulation diminished, there is no potential for growth. There has been some success in children,¹¹² but follow-up is limited.¹⁰⁴ More studies will be necessary to determine the long-term success of this technique.

For reconstruction of the right ventricular outflow tract, biologic valves including homograft valved conduits, and xenobioprosthetic valves, are most commonly used. Biologic valves have longer durability in the lower pressured pulmonary position compared to any position in the systemic circuit, favouring the use of biologic over mechanical valves. Furthermore, the risk of anticoagulation is avoided. Homograft conduits have excellent handling qualities, conform to the anatomy, and facilitate achievement of haemostasis. Limited durability, however, can be a problem. Homografts are commonly used for reconstruction of the right ventricular outflow tract. Early valvar insufficiency and obstruction have been reported.^{113–115} In some children, homografts undergo severe calcification, with accompanying shrinkage, that can result in obstruction. Calcification appears to be more accelerated in younger children.^{114,116–118} Incompatibility between donor and recipient have been proposed as contributing factors to this calcification and failure of the graft.^{116,119–121}

An alternative to homografts is use of the bovine jugular venous conduit (Contegra, Medtronic, Minneapolis, MN) (Fig. 13-11). The Contegra graft has been used in reconstruction of the outflow tract in patients with common arterial trunk, tetralogy of Fallot, the Ross procedure, and pulmonary atresia.^{122–127} Early and mid-term haemodynamic results are favourable,¹²⁷ with one study

showing valvar regurgitation to be absent in almost half of patients at a mean follow-up of 26 months.¹²⁵ In the largest series reported to date, with a mean follow-up of 2.1 years, there was no relevant gradient detected at the level of the valves, and minimal valvar insufficiency.¹²⁷ In the large prospective multi-centre study conducted by the Congenital Cardiac Surgeon's Society, the bovine jugular vein fared well, with a lower probability of progressing to more severe forms of severe regurgitation than other types of conduit.^{128,129} Aneurysmal formation,^{113,130} and a particular tendency for distal stenosis,¹²³ however, have been reported, though it is difficult at the current time to determine if these incidences are higher than those seen with homografts.

The use of small conduits is not surprisingly a risk factor for failure,^{115,131} but interestingly oversizing the valve by more than a z score of 2.7 has also been shown to be a risk factor for early failure.¹³¹ This trend was confirmed in the study coordinated by the Society of Congenital Heart Surgeons, where outcomes were better when sizes with z scores between 1 and 3 were chosen.¹²⁹

There is general agreement that a bioprosthetic valve is the conduit of choice in the tricuspid position when the native valve cannot be repaired.^{132,133} Bioprosthetic valves appear to fair better in this position than in any other position, with freedoms of reoperation reported at $97.5\% \pm 1.9\%$, and $80.6\% \pm 7.6\%$, at 1 and 5 years, respectively.

Valvar Repair

As discussed in the preceding section, options for replacement of valves are limited during childhood. Repair, if feasible, preserves the potential for growth, avoids anticoagulation, and also the need for valvar re-replacement. The disadvantages of repair include residual lesions, such as stenosis and insufficiency, and limited durability. Decision-making regarding the suitability of a lesion for repair is complex, and must take into account the pros and cons outlined above, as well as the specific lesion and the ability of the surgeon. Repair of the mitral valve is commonly performed, and uses techniques that borrowed from the experience in adults, as well as techniques that have been developed from repair of atrioventricular septal defects. Repair of the mitral valve is frequently successful and durable.^{134,135} In contrast, replacement of the mitral valve necessitates a repeated replacement in almost three-quarters of patients.¹³⁶ Mitral valvopathy amenable to surgical intervention may be the result of rheumatic heart disease, acquired and congenital cardiomyopathies, Marfan's disease, Shone's complex, and congenital mitral

Figure 13-11 A, A bovine jugular vein graft. Note the tricuspid venous valve. B, The valve is contained within a length of jugular vein that can be tailored to the specific anatomic requirements of the patient. (Reproduced with permission from Medtronic, Inc., Minneapolis, Minnesota.)

stenosis. Techniques for repair vary depending on the aetiology of the pathology.¹³⁵ For repair of mitral stenosis, techniques include commissurotomy, valvoplasty, cordal fenestration, and splitting of papillary muscles. For mitral insufficiency, techniques include repair of clefts, resection, shortening, or augmentation of leaflets, cordal shortening, annuloplasty, and creation of a double orifice.¹³⁷ In general, mortality is low with repair in the setting of biventricular circulations.^{138–141} In those with a functionally univentricular circulation, in contrast, repair carries a higher mortality.¹³⁵

Repair of the aortic valve is less well accepted than that of the mitral valve, albeit that experience is accumulating.^{142–148} Over the last decade, experience and success with repair have improved.^{146–149} Techniques include repair of valvar perforations, suspension of prolapsed leaflets, annuloplasty and extension of leaflets with pericardium.¹⁴⁶ In particular extension of the leaflets has been used with success in patients with rheumatic aortic valve disease, with 90% of patients free from valvar related complications at 7 years. Extension has also been applied to patients with congenital pathology with improving results.^{150,151}

STRATEGIES FOR CARDIOPULMONARY BYPASS AND PERFUSION

Surgical intervention inside the heart or on the great vessels normally requires significant interruption of flow of blood in regions of the surgical field to achieve adequate visualisation. To permit a more controlled surgical approach, extracorporeal circulation and oxygenation of blood has been developed. During cardiopulmonary bypass, venous blood from the great veins or right atrium is routed through an oxygenator or artificial lung, and reinfused into the aorta. A variety of specific techniques are used for cannulation and perfusion. These are intended to deliver oxygenated blood into the patient at a rate sufficient to fully support the function of the bodily organs for the duration of the surgical repair, and

as such have permitted the development of extraordinary surgical reconstructive procedures. Optimal strategy permits extensive surgical intervention, with largely predictable freedom from permanent injury to the organs. Planned and unplanned modifications of techniques, however, may place organs at the risk of ischaemia.^{152,153} Additionally, the nature of the interactions of blood with non-endothelialised surfaces, and the effects of associated alterations in temperature and pulse during bypass, make the technique a pathway for direct inflammatory and ischaemic injury.¹⁵⁴

The Circuitry of Cardiopulmonary Bypass

One task of the perfusionist is to tailor the circuit to the specific needs of the individual child. The variability of size, anatomy, and pathophysiology in this population necessitate the use of a great number of products. Large extracorporeal surface areas and prime volumes have been identified as potential contributors to complications following bypass.¹⁵⁵ Multiple sizes of oxygenators, heat exchangers, reservoirs, and other components have been designed to address these issues. Much of the research and development for the child has focused on reduction in surface area and volume to reduce total prime volume, surface area, and biologic incompatibility.^{156,157}

It is advisable for the circuits at a given institution to be organised in the same manner, facilitating the ability of perfusionists to provide safe and consistent service to all patients. A common configuration for bypass is to use bicaval cannulation with a single venous line for drainage into a hardshell venous reservoir with an integrated cardiomy reservoir (Fig. 13-12). A typical strategy for a cardiac cannulation is shown in Figure 13-13. A roller pump is used to pump deoxygenated blood from the reservoir through a hollow fibre oxygenator with an integrated heat exchanger. Blood exiting the oxygenator passes through an arterial line filter, and returns to the patient via the arterial cannula placed in the ascending aorta.

Figure 13-12 A simplified schematic of the components of a typical cardiopulmonary bypass circuit. A roller pump, an oxygenator, a heat exchanger, a venous reservoir, and a filter are included. IVC, inferior caval vein; SVC, superior caval vein.

Figure 13-13 A common technique of cannulation. Cannulation for an arterial switch is shown. Venous drainage is accomplished with separate venous cannula for the superior caval vein (SVC) and inferior caval vein (IVC). Oxygenated blood is infused via the arterial cannula positioned at the junction of the ascending aorta and aortic arch. The cross clamp has been applied isolating the coronary arteries for delivery of cardioplegia via a cannula in the proximal ascending aorta. Left ventricular distension is avoided by placing a left ventricular (LV) vent through the junction of the right superior pulmonary vein and left atrium, advancing it across the mitral valve into the left ventricle. (Reproduced with permission from Tweddell JS, Litwin SB: Transposition of the great arteries. *Operative Techniques in Thoracic and Cardiovascular Surgery: A Comparative Atlas* 7:49–63, 2002.)

Additional roller pumps provide active suction for use as field suckers, a left ventricular vent, or a vent in the aortic root. A variety of pressure transducers, level detectors, bubble detectors, and in-line blood gas analysers are used for enhanced precision and safety.

Oxygenators

Hollow fibre membranes are manufactured to mimic the pulmonary capillary bed by packing together microporous fibres in a spiral fashion.¹⁵⁸ Gas delivered to the oxygenator can be manipulated by the perfusionist to optimise oxygenation and removal of carbon dioxide. Anaesthetic vapours are commonly delivered via the membrane oxygenator, although the specific function for transfer of different vapours and oxygenators is variable. Surfaces exposed to the blood can be coated with some form of a biomimetic treatment. Several types of treatments are available, all having the goal of increasing the biocompatibility of the circuit, reducing damage to blood, and minimising the impact of bypass on the inflammatory response.¹⁵⁷

Reservoirs

Two types of reservoirs are utilised, venous and cardiotomy. The former is a collection chamber only for the venous blood. The latter collects all shed blood returning

from the operative field via cardiotomy suction and the left ventricular vent. Both reservoirs are filtered. The cardiotomy filters are designed to remove debris such as tissue, fat, macrothrombi and suture material.¹⁵⁸ Many reservoirs are available that combine the venous and cardiotomy suction as a single unit. In this configuration, the separation of the chambers is made internally. After the filtration process, their volumes combine into a single outlet, which simplifies connections and permits visualisation of air and the level of fluid in the reservoir. According to the latest published survey, nine-tenths of paediatric institutions in North America use hardshell venous reservoirs.¹⁵⁹

Pumps

Although many types of pumps have been described in the literature, there are primarily two types of arterial pumps in use today, namely roller and centrifugal. Roller pumps contain a length of tubing located inside a curved raceway. This raceway is placed at the travel perimeter of rollers mounted on the ends of rotating arms positioned opposite each other. These rollers are mounted in such a way that one roller is compressing the tubing at all times. By compressing a segment of the blood-filled resilient tubing, the pump pushes blood ahead of the moving roller, producing continuous flow. The output of the roller pump is determined by the revolutions per minute of the pump, and the volume displaced with each revolution. This stroke volume depends on the internal diameter of tubing and the circumferential length of the raceway.¹⁶⁰ The roller pump head is reusable. The flow rate is simple to determine, by multiplying stroke volume by the revolutions each minute, and multiple sizes of tubing can be used in the same pump, making it applicable to patients of all sizes. These pumps, however, do have disadvantages. The pump displaces in positive fashion, so it will pump air as well as blood, necessitating the need for a system to detect bubbles. It is an occlusive pump, so pressure transducers must be connected to the system to detect excessive pressures, reducing the risk of particulate micro-embolisation from tubing spallation, shear-induced blood damage or possible rupture. Establishment of the optimal setting for occlusion is imperative for accurate calculation of rates of flow, and to minimise blood trauma.

Centrifugal pumps consist of an impeller arranged with either vanes or a nest of smooth plastic cones inside a plastic housing. The sterile, disposable impeller is coupled magnetically with an electric motor spinning in the drive console. When the impeller rotates rapidly, it generates a pressure differential, causing blood to flow.¹⁶⁰ Centrifugal pumps are non-occlusive and pressure dependent. They generate increased flow when either the preload increases, or the afterload decreases. The non-occlusive nature of the pump eliminates the possibility of tubing wear, spallation, and excessive pressure in the lines, but since they are pressure dependent, a flow transducer is necessary to determine accurate rates of flow. If the pump slows or stops, reverse flow can occur. Centrifugal pumps require more expensive disposable parts compared to the roller pump. As a result of the described limitations of centrifugal pumps, a recent survey found that roller pumps were the predominant pump device in nine-tenths of paediatric centers.¹⁵⁹

Filters and Haemoconcentrators

In addition to the cardiotomy and venous reservoir filters mentioned previously, all but 2% of paediatric institutions use arterial line filters as a last line of defense against

gaseous and particulate microembolisation.¹⁵⁹ They come in a variety of sizes, with pre-established limits to rates of flow. They require additional volume to prime, but are excellent gross bubble traps. Because they are micropore filters, they are susceptible to obstruction. Manufacturers recommend placing a clamped bypass line around them that can be opened if the filter becomes obstructed.

Haemoconcentrators allow the perfusionist to remove water and other electrolytes, such as potassium, from the blood. They contain hollow fibres similar to those within a dialysis filter. Blood passes through the inside of hollow fibres and light vacuum is placed on the outside. Everything smaller than the size of the pores of the semipermeable membrane will be extracted, including water, electrolytes, some cytokines and drugs, and everything larger than the pores will remain in the blood stream, including red cells, platelets and most plasma proteins. Significant haemoconcentration can be achieved. Some heparin will be removed; thus adequacy of heparinisation must be monitored regularly.¹⁶⁰ The haemoconcentrator can be used at any time during the case, provided there is sufficient volume in the venous reservoir. This is the same type of filter used to perform modified ultrafiltration.

Conduct of Cardiopulmonary Bypass

Rates of Flow

Although the determinants of delivery of oxygen, namely concentration of haemoglobin, saturation of oxyhaemoglobin and rates of flow, are more easily measured during cardiopulmonary bypass than at any other time in the life of a neonate or infant, the adequacy of delivery of oxygen should always be continuously monitored and adjusted to avoid overt or occult injury to the organs throughout the perioperative period.^{161,162} Rates of flow have typically been guided by nomograms based on body weight or surface area, and Fick's principles of delivery of oxygen and metabolism.¹⁶³ The regional distribution of blood during cardiopulmonary bypass is related to host and technical factors, and the probability of adequate flow to the whole body or organs is related to the total rate of flow.^{162,164–167} Typically, full flow refers to a perfusion index of 2.8 to 3.6 L/m²/min, which corresponds to 150 to 200 mL/kg/min in a neonate. Low flow is delivered at varying hypothermic conditions to afford metabolic protection and typically refers to rates of between one-quarter and half of full flow.¹⁶⁷ The rates of flow to the whole body necessary to maintain adequate cerebral perfusion range from 30 to 80 mL/kg/min.^{168,169} Isolated perfusion of organs during bypass is governed by the relative distribution of vascular resistance. Reduction in temperature to 16° C to 20° C allows termination of flow for a limited amount of time to permit unobscured access to the surgical field, a condition referred to as deep hypothermic circulatory arrest. The safe duration of deep hypothermic circulatory arrest in any individual patient is unknown and highly related to the determinants of delivery of oxygen.¹⁷⁰ The deleterious effects of lowered flow may be more pronounced after hypothermic arrest,¹⁷¹ when a higher perfusion pressure is necessary to re-establish cerebral flow.¹⁷² Because of variability between patients and techniques it is advisable to measure indicators of cerebral oxygenation. Manipulation of the independent determinants of delivery of oxygen, such as haemoglobin, and partial pressures of carbon dioxide, can be used to restore cerebral oxygen delivery.¹⁷³

Haemodilution

Haemodilution has almost universally accompanied cardiopulmonary bypass because of the desire to prime extracorporeal circuitry with products other than blood. Rheologic considerations for microvascular flow during hypothermia have supported this approach, and are thought to outweigh the reduction in delivery of oxygen associated with the anaemia produced by haemodilution. The weight of evidence, however, supports limiting haemodilution in neonates and children, targeting a haematocrit of at least 30% even during deep hypothermia.^{174–176} While variations in prime solutions are mainly targeted at manipulation of electrolytes, oncotic pressure, and haemoglobin, the effects on prothrombotic, procoagulant and anticoagulant factors should also be recognised as important effects of haemodilution, and calculated based upon estimated blood volume and circuit volume for each patient.

Temperature Regulation

Hypothermia reduces both the cerebral metabolic rate and the availability of oxygen for transfer to the brain. The effects on cerebral metabolism are complex. The metabolism of brain and other tissue is reduced with reduction in body temperature.¹⁷⁷ Most data suggests an inverse exponential relationship, with as much as a 3.5-fold reduction in metabolism for a reduction of 10° C in temperature, the so-called Q10.¹⁷⁸ Others have found a Q10 as low as 2.3.¹⁷⁹ The bulk of evidence suggests a nearly-inverse exponential reduction in metabolism is reduced by an average of 2.8 fold for a 10° C change in temperature.¹⁸⁰ The result of metabolic suppression with hypothermia is that cerebral oxygen extraction is reduced, while flow of blood is allowed to be autoregulated, whether measured by saturations in the jugular bulb^{180,181} or near-infrared spectroscopy.^{182,183} Because temperature affects the solubility of oxygen and carbon dioxide in solution, and their interaction with haemoglobin, changes in temperature are coupled with changes in gas tensions and pH. In a broad range of studies, the independent effect of pH is small compared to the effect of temperature, with a small reduction in oxygen consumption in more acidotic environments.¹⁸⁰ Because pH responsiveness of the cerebral vasculature remains in effect at hypothermia, however, control and manipulation of pH is a critical part of temperature management.

The coupling between cerebral metabolism and blood flow seems to be reasonably maintained in the temperature range of 32° C to 37° C.^{184–189} Below 30° C, however, uncoupling is commonly demonstrated, regardless of pH, such that the metabolism is reduced more than blood.^{181,190–192} The solubility of oxygen in plasma, and the affinity of haemoglobin for oxygen, are both increased with hypothermia, such that availability of oxygen in the tissues is reduced at any given rate of flow, the Bohr effect. The increased ratio of cerebral flow to metabolism with hypothermia is commonly viewed as cytoprotective from an energetic viewpoint,¹⁸⁰ but the decreased availability of oxygen may negate this apparent metabolic protection.^{193,194} The result of increased solubility and leftward oxyhaemoglobin shift is that the fall in cerebral oxygenation with ischaemia is not attenuated by hypothermia, even though saturations of haemoglobin are better maintained.¹⁹⁵ Altogether the cytoprotective effects of mild hypothermia exceed measurable metabolic effects and likely involve other mechanisms including alterations in gene expression.¹⁹⁶

In practical terms, schemes for cooling are relatively standardised in most institutions. The complexity of the defect to be corrected or palliated dictates the strategy for the temperature used during bypass, albeit that compounding anatomic features such as the presence of aortopulmonary collateral arteries may influence the strategy. Typically, mild hypothermia, at 37° C to 32° C, will be employed for simple defects such as atrial and ventricular septal defects. Moderate hypothermia, between 32° C and 28° C, is used for more complex lesions such as atrioventricular septal defect or tetralogy of Fallot. Deep hypothermia, from 28° C down to 18° C, is reserved for the most complex lesions requiring a period of circulatory arrest, such as palliation of hypoplasia of the left heart, repair of interrupted aortic arch or correction of discordant ventriculo-arterial connections.

Acid-Base Management

The management of blood gases during cardiopulmonary bypass is intertwined with that of temperature and has been widely investigated and debated. The complexity ensues because metabolic rate, the solubility of gases in blood, the ionisation of water, and therefore the pH of electroneutrality, the ionisation of intracellular buffers, and the affinity of both oxygen and carbon dioxide for haemoglobin are all dependent on temperature.¹⁹⁷ There are two strategies developed for management. A pH-stat strategy maintains normal levels of carbon dioxide and hydrogen ions when measured at hypothermia, or temperature corrected. An alpha-stat strategy maintains normal gas tensions and acid base balance when measured at normothermia, or temperature uncorrected. The alpha-stat approach is associated with minimal metabolic suppression, and represents the physiologic situation in homeotherms with temperature gradients across parts of the body, but with thermoregulation maintained. The pH-stat approach is associated with metabolic suppression, and more closely mimics the metabolic milieu of hibernation with induction of metabolic suppression.¹⁹⁸

The pH affects the ratio of flow of blood to metabolism.¹⁸⁵ While levels of adenosine triphosphate in the brain are maintained during alpha-stat cooling,^{183,199} with pH-stat cooling there is evidence of luxury perfusion. At temperatures below 30° C, blood flow is pressure-passive over a wider range of metabolism, with overperfusion evidenced by the appearance of oedema.²⁰⁰ The increased flow with pH-stat strategy is widely utilised to increase uniformity of cerebral cooling, oxygenation^{174,183,201–205} and metabolic suppression.^{182,197,205} There is evidence of improved outcome in children subjected to deep hypothermic circulatory arrest^{206–208} or low-flow bypass when using the pH-stat strategy.^{209–211} Evidence also exists for improved myocardial function with pH-stat techniques.²¹² The effects of pH on non-cerebral tissue are also important in determining the distribution of flow on cardiopulmonary bypass. A pH-stat strategy directs more blood to the brain in the presence of aortopulmonary collateral connections.¹⁷⁴ Approaches which combine pH-stat strategy for cooling with alpha-stat strategy for maintenance of high-flow hypothermic perfusion may represent a compromise between inadequate delivery of oxygen and metabolic suppression, and overperfusion-related formation of oedema and post-acidotic increased cerebrovascular resistance.^{181,213}

Cerebral Protection and Anaesthesia

Suppression of cerebral consumption of oxygen occurs with both vapour and barbiturate-based anaesthesia, and hypoxia tolerance, based upon lactate production, is enhanced.²¹⁴ The suppression of metabolism by anesthetic vapours is accompanied by maintenance of high energy phosphates, indicating desirable energetic balance.²¹⁵ Because vapour agents are also cerebral vasodilators, the ratio of cerebral flow to metabolism is higher with these agents, and the increase in cerebral flow may be maintained for hours.^{216–218} Suppression of thermoregulatory²¹⁹ responses to hypothermia may be an important role for the salutary effect of lower-stress anaesthetic strategies on survival in complex repairs.²²⁰ Inhibition of K-ATP channels by vapours may induce preconditioning, reduce reperfusion injury and reduce apoptosis in ischaemic models.^{221–223} The vasodilatory effects of vapour anesthetics can be expected to improve the uniformity of cerebral cooling and warming. Withdrawal of anaesthetic vapour is likely to induce cerebral vasoconstriction in a fashion parallel to the vasodilation seen on acute introduction. Because the neonatal brain is particularly vulnerable to apoptosis via excitotoxic injury, vapour anesthetics might be particularly indicated.^{222,224–227}

Pathways of Cerebral Injury Related to Bypass

Cerebral injury is deterministically related to the delivery of oxygen, with irreversible necrotic cell death resulting from a sustained reduction in delivery below 20% of normal.^{227,228} Rates of delivery above half baseline typically do not result in injury, while delivery rates of one-quarter to half of the normal range result in cellular injury, whose outcome is modifiable by other factors, such as temperature and free-radical scavenging, even when applied after the insult.²²⁹ Apoptotic cell death ensues hours to days after subnecrotic hypoxic-ischaemic injury in susceptible populations of cells, and there exists a spectrum of ischaemic and apoptotic death in both focal and global models of ischaemia.^{225,228,229} Amplification of injury through excitatory amino acid neurotransmitter-related calcium-dependent cascades of uncontrolled neuronal depolarisation may play a role in both necrotic and apoptotic cell death.²²⁸ Modification of excitotoxicity can be demonstrated with glutamate receptor antagonists such as ketamine and dextromethorphan, receptor agonists such as anesthetic vapours and barbiturates, magnesium, and hypothermia.²²⁸ Although therapeutic trials have generally been disappointing in profound ischaemia, an incremental effect is likely in more moderate injury.^{230,231}

Although hypothermic circulatory arrest represents an obvious example of global ischaemia, it is likely that regional partial ischaemia exists during many phases of bypass and the perioperative period. In an animal model of tissue oxygenation during changing conditions of bypass, a range of levels of oxygen in the tissues was demonstrated using the phosphorescent quenching technique, even during high-flow bypass. More hypoxic regions appear during low flow and hypothermic circulatory arrest.²³² The cerebral circulation is susceptible to hypoxic injury throughout the perioperative period, and partial ischaemia is possible even during high-flow bypass, with neuronal fate modifiable by postoperative factors.^{229,233,234}

Myocardial Protection and Cardioplegia

Initiation of cardiopulmonary bypass often has myocardial protective effects if the heart is properly unloaded by enhancing the availability of oxygen delivered through the

coronary arteries and reducing consumption of oxygen. Hypothermia is a core component of myocardial protection. It further decreases consumption of oxygen, and preserves stores of high energy phosphates. Myocardial work can be further reduced by inducing a hyperkalaemic arrest via the administration of cardioplegia. The coronary arteries are isolated from the distal aortic circulation by placement of an aortic crossclamp distal to the cannula used to deliver cardioplegia. Cold solutions are then immediately delivered at 4° C. Aortic valvar competence is necessary to ensure the cardioplegia flows to the coronary arteries and not into the left ventricle. If the aortic valve is not competent, the aortic root can be opened and cardioplegia can be delivered directly into the orifices of the coronary arteries. Cardioplegia can also be delivered in a retrograde fashion via a catheter placed in the coronary sinus, as long as the sinus is not receiving blood from a left superior caval vein. Retrograde cardioplegia is often used as a supplementary method of cardioplegia, even when antegrade cardioplegia is possible.

Localised myocardial hypothermia can be achieved with cooling jackets and placement of ice slush in the pericardial space. This technique should be judiciously used, however, as it can result in injury to the phrenic nerves.¹⁵⁹ As an adjunct to hypothermia, the high concentration of potassium in the cardioplegia results in myocardial electromechanical silence and diastolic arrest. The initial arresting dose of cardioplegia at our institution is 35 mL/kg delivered at a pressure in the aortic root of 80 to 120 mm Hg. Maintenance doses of 15 mL/kg are given every 15 to 20 minutes thereafter until the repair is complete.

A crucial component of successful myocardial protection is ventricular decompression. Myocardial consumption of oxygen and impedance to subendocardial flow of blood is significantly reduced by lowering the ventricular mural tension.²³⁵ Decompression is accomplished most commonly with the use of a catheter introduced through the right superior pulmonary vein and the left atrium. The catheter passes through the left atrium, across the mitral valve into the left ventricle. Constant suction is applied to the catheter with the use of a designated roller pump on the bypass machine. Blood returning from the venting catheter is recycled into the cardiectomy reservoir as discussed previously.

Anticoagulation

Although other anticoagulants have been used in special situations,^{236–238} heparin is overwhelmingly the most commonly administered anticoagulant.^{239,240} Heparin has a rapid onset of action, is easily reversed with protamine, and has important anti-inflammatory effects.^{241,242} Dosing regimes include simple weight-based schemes, titration to a functional endpoint depending on activated clotting time, and measurement of concentrations with more complicated predictions. Convincing evidence for superiority of approaches is lacking. The gold standard of determining adequate anticoagulation suitable for bypass has been the activated clotting time. This test, however, does not take into account the effects of volume of blood, previous exposure to heparin, deficiency of antithrombin III, hypothermia or haemodilution. The Hepcon heparin management system (Medtronic, Inc. Minneapolis, MN) uses a pre-bypass titration of protamine to determine a patient-specific concentration of heparin to be maintained throughout the bypass

run. While on bypass, samples of blood are taken every 30 minutes to determine both concentrations of heparin and activated clotting times. Additional need for heparin is based on maintaining an adequate concentration regardless of an extended activated clotting time. The Hepcon device calculates the dose of protamine needed to reverse heparin based on the circulating concentration of heparin at the end of the bypass run. The thrombotic, embolic, and inflammatory complications of cardiopulmonary bypass are increased with lower heparin effect. Adequate anticoagulation is crucial, otherwise intravascular coagulation, thrombosis, oxygenator dysfunction, and consumption of clotting factors may occur.¹⁶⁰ Heparin-induced thrombocytopenia, still an unusual complication in infants and children, may be more difficult to recognise.²⁴³

Strategies for Cooling

Surface cooling can begin with induction of anaesthesia, which promotes loss of heat and impairs thermoregulatory responses. A reduction in temperature to 35° C is generally well tolerated, and may confer protection against ischaemia in the period prior to bypass by metabolic suppression and alteration of responses to cellular injury. Further cooling on bypass is targeted based upon the anticipated level of flow required to complete the surgical repair. If deep hypothermic circulatory arrest is anticipated, a nasopharyngeal temperature of 18° C is generally the target, with evidence for increased complications at significantly higher and lower temperatures. Active cooling should be accompanied by measures of the adequacy of uniform cerebral cooling, for which measurements of surface temperature are inadequate.²⁴⁴ Other indicators include jugular venous saturation, the electroencephalogram, and near infrared spectroscopy, from which evidence of metabolic suppression can be more directly ascertained.^{245–249} At least 20 minutes of cooling is associated with improved outcome if hypothermic circulatory arrest is utilised.^{250,251} A high flow hard-cooling pump strategy is necessary to raise the jugular venous saturation above 95%.¹⁸¹ Measures which increase cerebral blood flow, such as a pH stat strategy, can improve brain cooling as previously discussed.¹⁸²

Recent evidence-based reviews cite no advantage to hypothermia in either neurosurgery or open heart operations.^{252,253} Since many operations can be completed without significant interruption in flow of blood, this finding may be unsurprising.²⁵⁴ These meta-analytic reviews, nonetheless, fly in the face of overwhelming laboratory and clinical evidence of protection from ischaemic injury with hypothermia in global ischaemia.^{255–259} Because the metabolic benefit of cooling and hypothermia is lost during rewarming, which may be superimposed on a period of reduced delivery of oxygen, a greater risk of ischaemia to both heart and central nervous system occurs with rewarming.²⁶⁰ Given the multiple factors that may cause unexpected disruption in perfusion at full flow, some emergent in nature, most centers continue to use mild or moderate hypothermia as a protective adjunct to cardiopulmonary bypass without planned reduction of flow or circulatory arrest.^{254,261} While the overall perioperative inflammatory response, although reduced during hypothermia, does not seem to be altered by strategies depending on temperature,²⁶² moderate hypothermia probably induces cellular adaptations at the transcriptional and translational level that result in survival programming.^{263,264}

Deep Hypothermic Circulatory Arrest

Deep hypothermic circulatory arrest was first developed as a neuroprotective strategy when continuous perfusion could not be maintained. Currently, there is intense debate over the degree of protection offered by hypothermic circulatory arrest compared to hypothermic perfusion. The Boston circulatory arrest trial demonstrated that a strategy utilising hypothermic circulatory arrest compared to even low-flow bypass is associated with more immediate cerebral brain injury. Patients undergoing hypothermic circulatory arrest had more seizures, an increased tendency to have abnormal electroencephalograms,²⁶⁵ and lower developmental performance at 1 year.¹⁶³ Both groups underperformed at 8 years.¹⁶⁵ Prolonged hypothermic circulatory arrest, greater than 40 minutes at 18° C, is associated with impaired neurodevelopmental outcome.^{266,267} The relationship between a shorter duration of circulatory arrest and outcome is uncertain, but examination of the data from the Boston trial reveals a range of outcomes across the range of circulatory arrest intervals, indicating a multiplicity of determinants of outcome, including individual biologic susceptibility.²⁶⁸ The safe duration of hypothermic circulatory arrest is related to the rate of use of oxygen from available stores, and can be predicted on the combination of haemoglobin, temperature, pH, and time. It is reflected uniformly by the cerebral saturation of oxygen as measured by near infrared spectroscopy.^{166,170,199} The distribution of tensions of oxygen in the brain during hypothermic circulatory arrest is higher, and apoptotic regulators are lower, with a pH-stat strategy for cooling, predicting a longer safe time for hypothermic circulatory arrest.^{171,269}

In an individual, the use of near-infrared spectroscopy can guide the safe duration of hypothermic circulatory arrest by limiting the time of low cerebral oxygenation.^{173,174} With optimal cooling to 18° C and a circulatory arrest time of less than 30 minutes, cerebral injury is unlikely.²⁶⁷ Moderate and profound hypothermia may initiate protective proapoptotic mechanisms that off-set the deleterious effects of sublethal ischaemic times.²⁷⁰ During longer periods of circulatory arrest, intermittent reperfusion at intervals of 15 to 30 minutes has been demonstrated to maintain cytoarchitecture, cerebral distribution of oxygen, and indicators of excitotoxicity in animals.^{271–273}

Selective Antegrade Cerebral Perfusion

Because of the variability in time necessary to complete repair, and the limited duration of deep hypothermic circulatory arrest, strategies have been employed to maintain continuous delivery of oxygen to the brain. Selective antegrade cerebral perfusion via the brachiocephalic artery has become widely used.^{274–279} The optimal strategy for this technique remains poorly characterised, because measurements of cerebral blood flow are not readily available, and autoregulation may be altered during cold cardiopulmonary bypass and selective perfusion.²⁸⁰ Most centers use pH-stat cooling to a target of 20° C to 26° C as in anticipated circulatory arrest, followed by direct perfusion of the brachiocephalic artery. Flow rates of 10 to 80 mL/kg/min have been described.¹⁷³ Flow rates of less than 30 mL/kg/min, however, are not likely to provide adequate cerebral blood flow to open all capillary beds.^{281,282} Moreover, the increased affinity of haemoglobin at hypothermia may limit availability of oxygen during perfusion, partially off-setting the anticipated reduction in metabolism. The

optimal temperature is not known, and is undoubtedly related to strategies of flow, although evidence supports maintenance of a deep hypothermia should a period of circulatory arrest be necessary.^{283,284} Techniques to monitor adequacy of cerebral flow during this technique include trans-cranial Doppler and near infrared spectroscopy.¹⁷³

Experimental models of continuous cerebral perfusion compared to hypothermic circulatory arrest show improved cerebral oxygenation,^{169,285} better post-perfusion haemodynamics,²⁸⁶ reduced apoptosis²³² with less ischaemic injury, and improved outcomes.^{284,287,288} A recent comparison of cerebral perfusion versus hypothermic circulatory arrest in neonates undergoing reconstruction of the aortic arch showed no difference in neurodevelopmental outcome at 1 year. The technique for cerebral perfusion in this study, however, used a rate of flow of only 5 to 20 mL/min, and measures of cerebral oxygenation were not reported.²⁸⁹ Because the rates of flow in those receiving cerebral perfusion were not likely to result in adequate delivery of oxygen, the results are not surprising, showing no difference between complete ischaemia and inadequate perfusion. Outcomes utilising an alternative approach utilising high-flow perfusion of 50 to 70 mL/kg/min show no evidence of ischaemic injury on postoperative magnetic resonance imaging.²⁹⁰

Because bypass exposes the body to a huge inflammatory stimulus, there may be a relative disadvantage of prolonged cerebral perfusion compared to circulatory arrest of shorter duration.^{291–293} At present, there exists no direct comparison between cerebral perfusion at rates of flow with measured adequate cerebral oxygenation and deep hypothermic circulatory arrest. The optimal pH strategy for continuous selective perfusion is also debatable and conflicting, with some evidence favouring an alpha-stat approach,²⁹⁴ and other evidence favoring a pH-stat approach.^{171,269} Because of the inherent risk of prolonged ischaemia, and the unpredictable delayed effects of hypothermic cerebral perfusion and circulatory arrest on postoperative flow of blood to the brain, we favour strategies that rely both on measurement and maintenance of cerebral oxygenation throughout the operative period.²⁹⁵

Pharmacologic and Mechanical Adjuncts

Corticosteroids

Pre-treatment with corticosteroids is widely used, with broad but conflicting evidence for alteration of outcome. Pre-treatment in adults reduces postoperative levels of tumour necrosis factor- α , interleukin-6, the incidence of atrial fibrillation, and markers of myocardial ischaemia.^{296–299} Evidence exists for both exacerbation and amelioration of hypoxic and ischaemic cerebral damage.^{300–303} It was shown that two doses of 30 mg/kg methylprednisolone may ameliorate the inflammation-related delayed reflow and cerebral metabolism after hypothermic circulatory arrest.³⁰⁴ The membrane-stabilising effect may reduce excitatory neurotoxicity,³⁰² and perivascular oedema may be reduced,³⁰⁵ but necrotic cell death appeared to be unaffected, and apoptotic cell death may be increased.^{306,307}

Aprotinin

Aprotinin is a serine protease inhibitor with a wide range of enzymatic targets. It has approval from the Food and Drug Administration to reduce the loss of blood during reoperation in adults undergoing bypass, and is widely used

for conservation of blood, and for its anti-inflammatory effects.^{153,308–310} As with other therapies aimed at modification of the inflammatory response, both desirable and undesirable outcomes may result, including an apparent increase in renal dysfunction related to hypotension.³¹¹ Studies in adults have shown a reduction in both cerebral and myocardial injury in patients receiving aprotinin. This finding has been linked putatively to the anti-inflammatory effect of endothelial protection.^{312,313} Administration of aprotinin to piglets undergoing hypothermic bypass and hypothermic circulatory arrest resulted in greater preservation of endothelial-dependent vasodilation, improved cerebral blood flow, and produced faster recovery of cerebral stores of high energy phosphate,³¹⁴ underscoring the impact of inflammatory microvascular injury in the pathophysiology of organ dysfunction following bypass.

Alpha-Adrenergic Blockade

The distribution of cardiac output is strongly influenced by the sympathetic nervous system, mainly through α -adrenergic mechanisms. Although deep anaesthetic strategies can alter the neurohumoral stress response to surgery,²²⁰ evidence exists for high levels of sympathetic response during cardiac surgery, regardless of the anaesthetic regimen.³¹⁵ We have shown an improvement in whole-body economy of oxygen using phenoxybenzamine that permits and necessitates a strategy of bypass at high rates of flow.^{316,317} In the presence of milrinone, α -adrenergic blockade is more effective than nitrovasodilators in improving flow both on³¹⁸ and off bypass.^{281,319,320} Although outcomes seem improved with this approach,^{317,321} a randomised outcome trial is lacking.³²²

Control of Glucose

Evidence for a beneficial effect of glycaemic control in paediatric cardiac surgery is distinctly lacking. The neonatal brain and heart are poorly tolerant of hypoglycaemia, which has been related to seizure activity and poor outcome in a large retrospective study of intraoperative glycaemic patterns and neurologic outcome.³²³ In contrast to findings in adults, post-hypoxic supplementation of glucose may reduce neurologic injury in the developing brain.³²⁴ Insulin has anti-oxidative, anti-apoptotic pro-survival cell programming effects, independent of its glycaemic effects.^{294,325} Because deficiency of insulin is rare in infants and children, the role for exogenous insulin is not yet established.

Ultrafiltration

Modified ultrafiltration is a technique to remove excessive water from the body after restoration of the native circulation, but before removal of the cannulas used for bypass.^{326,327} As an incremental strategy in adults, modified ultrafiltration reduces morbidity and post-operative use of resources.³²⁸ In children, benefits include improved haemodynamics, pulmonary mechanics, and cerebral metabolism.^{329–333} Some of these effects may be achieved by other strategies to reduce the deleterious effects of bypass-related haemodilution and activation of blood products, including conventional ultrafiltration and strategies for reduction of the prime.^{334–336} A direct effect of modified ultrafiltration on inflammatory mediators, and on ultimate clinical outcome, is uncertain.^{337,338} Extreme reduction in the volume of prime volume miniaturisation of the circuit may eventually replace ultrafiltration.³³⁹ It is likely that a combination of ultrafiltration and incremental alterations in components of the circuit to improve biocompatibility can also improve outcomes.^{157,329}

Preconditioning

Ischaemic preconditioning, or induction of tolerance to prolonged ischaemia by brief exposure to ischaemia, has been observed in the myocardium, brain, liver, kidney, intestine, and skeletal muscle, and probably is a feature of all mammalian cells.³⁴⁰ The effect was first described by the observation of reduced size of infarcts after 40 minutes of coronary arterial occlusion if preceded by cycles of 5 minutes of occlusion.³⁴¹ The early protective window occurs within minutes, and fades within a few hours. A later second window of protection, or delayed preconditioning, opens about 24 hours after some preconditioning stimuli.^{340,342,343}

Early protective responses to sublethal ischaemia induce alteration in the flow of blood and metabolism. Within hours, signaling systems involving hypoxia-inducible factors and heat shock proteins confer resistance to apoptotic transformation.³⁴⁴ Features of this characteristic response can be induced by hypoxia-ischaemia, hyperthermia, hypothermia, hypoglycaemia, a range of drugs including K-ATP channel blockers, erythromycin, volatile anaesthetics, opioids, acetylsalicylic acid, glutamate, and erythropoietin, the latter having received much attention in recent clinical trials.^{345,346} The mediators of this response favouring survival can be released remotely from the target organ, and improved myocardial function has been demonstrated in humans after minimal ischaemia induced by a tourniquet placed on the leg.³⁴⁷ Induction of a common signaling pathway for survival of cells, as opposed to apoptosis, has been suggested as the underlying mechanism for these findings.^{348,349}

Considerations at the End of Bypass

Altered Cerebral Flow of Blood and Metabolism

The increased relative flow of blood to the brain induced by hypothermia can result in a postoperative increase in cerebrovascular resistance and cerebral oedema, although responsiveness to carbon dioxide is maintained.^{350–353} Some of this impaired flow may be due to microvascular occlusion, and can be ameliorated by treatments that reduce aggregation and adhesion of platelets, such as donors of nitric oxide, antagonists of thromboxane, and antiplatelet drugs.^{354–357} Modified ultrafiltration also seems to improve cerebral blood flow and metabolism, presumably by reduction of inflammatory mediators.³³²

Hypothermic circulatory arrest results in both loss of autoregulation and delayed reflow, with a prolonged suppression of flow of blood and uptake of oxygen.^{358–360} This delayed recovery of cerebral metabolism may exacerbate the neurologic injury related to circulatory arrest.¹⁶⁴ Suppression of metabolism during hypothermic circulatory arrest using a pH-stat strategy,²⁰¹ and maintenance of a higher postoperative haematocrit,³⁶¹ can, in piglets, partially ameliorate this metabolic derangement occurring after circulatory arrest. Postoperative arterial hypoxaemia exacerbates the arrest-related injury,³⁶² and maintenance of delivery of oxygen to the brain with mechanical assistance may be preferable to inadequate postoperative delivery.^{169,363} We have demonstrated that, following hypothermic circulatory arrest in neonates, inadequate postoperative economy for oxygen is related to poor late neurodevelopmental outcome, and that postoperative hypercapnia is protective in this setting.²³⁴ Continuous

cerebral perfusion does not eliminate the risk of post-operative cerebral desaturation,^{295,364} and the interaction between intraoperative management and post-operative flows of blood remains complex.

Postconditioning

Ischaemic postconditioning describes modification of injury by interventions applied just at the time of reperfusion, and was first observed with intermittent reperfusion.³⁶⁵

This may be a form of modified reperfusion, and has been observed with a variety of agents, including erythropoietin, insulin, and isoflurane, which are commonly administered in the operating room around the time of cardiopulmonary bypass and other ischaemic challenges.^{340,366,367}

While hypothermia and volatile anaesthetics amplify the protection afforded by preconditioning for tolerance of prolonged ischaemia, postconditioning seems to have limited effect after prolonged ischaemia.^{368–370} Remote postconditioning has been described via brief occlusion of leg or kidney perfusion just at the time of reperfusion of myocardium, yielding a reduction in the size of infarcts 48 to 72 hours later.^{345,371}

While the application of these techniques may seem simple, and associated with minimal risk, the clinical utility remains to be elucidated. Inadvertent conditioning may result from aspects of stimulations providing pre- and postconditioning commonly present throughout the operative period. The technique of intermittent reperfusion during prolonged hypothermic circulatory arrest²⁷³ may be a paradigm for both pre- and postconditioning. An acidotic perfusion milieu at the beginning of reperfusion may not only enhance flow, but may also be important in promoting ischaemic postconditioning and anti-apoptosis.³⁷²

Post-operative hyperthermia is common after cardiopulmonary bypass,³⁷³ and has been associated with poorer neurologic outcome.^{374,375} Attention to the control of temperature during rewarming, and immediately following bypass, can reduce the incidence of undesired hyperthermia. Induction of post-operative hypothermia should be strongly considered for patients experiencing uncontrolled or prolonged peri-operative ischaemia.³⁷⁶ Hypothermia may afford protection independent of its effects on cerebral blood flow and metabolism. The effects of hypothermia post-injury are likely due to reduction in apoptotic cell death, and thus both intra-operative and post-operative hypothermia may provide anti-apoptotic programming. Reduction in apoptotic cell death has been demonstrated using cerebral perfusion as a supportive strategy as opposed to hypothermic circulatory arrest.^{287,288} Post-operative mild hypothermia, and administration of albumin, are simple clinical interventions commonly applied which may alter outcome after incomplete ischaemia.^{229,377} Evidence of focal ischaemia from gas embolism or other causes should prompt consideration of hyperbaric treatment with oxygen.^{378,379}

Monitoring

Because a range of conditions can affect central haemodynamics, regional cerebral perfusion, cerebral metabolism, and flow metabolism coupling during cardiac surgery, cerebral oxygenation is likely altered in both predictable and unpredictable ways. Cerebral hypoxia, measured by jugular venous saturation or infrared spectroscopy, has been shown experimentally to be related to injury during ischaemia,^{174,380} with similar findings reported in humans.^{364,381} Hypoxic-ischaemic conditions

cannot reliably be identified by standard haemodynamic monitoring. Because aggressive prevention of overt and occult hypoperfusion improves outcomes,^{161,317,382} measurement of global and regional oxygenation is recommended as a method to prevent and treat unanticipated and unappreciated hypoxic-ischaemic conditions. This is especially crucial in the immediate perioperative period, when intervention to improve outcome is possible.^{382–385}

Intra-operative Echocardiography

Transoesophageal echocardiography has become a mainstay of intra-operative management of the patient undergoing cardiac surgery. Specific guidelines have been developed as to the indications for its use in children. There is general agreement that the technique is indicated in every child over 3 kg. Some centers use the system in any infant over 2.5 kg in whom a probe is easily placed. An echo is generally performed at the beginning of every case, both to confirm the anatomy previously detected by using transthoracic windows, and to obtain real-time orientation to dynamic structures. Intra-operatively, echocardiography can be important to verify that air has been cleared from cardiac chambers prior to allowing cardiac contractions and emergence from cardiopulmonary support. It can also be very useful in delineating the source of failure when a child is not able to be weaned from bypass (i.e., residual lesions). For instance, echocardiography is very useful when differentiating hypovolaemia from functional compromise and residual structural deficits. At the termination of the procedure, echocardiography is critical in verifying the adequacy of many repairs.³⁸⁶

Post-operative Extracorporeal Support

Short-term mechanical support is occasionally necessary following complex cardiac operations. The use of extracorporeal membrane oxygenation carries a reasonable expectation of recovery for small patients in cardiopulmonary failure. In the current era, the technique is an essential component of programmes undertaking complex congenital cardiac surgery.^{387,388} The circuit used by most centres is a direct descendant of the circuit initially developed for support of the neonate with pulmonary hypertension and persistent fetal circulation, and has the advantage of being standardised and well understood by the specially trained staff who manage the circuit.^{389,390} Key to its success was the development of the silicone membrane oxygenator, which extended the safe duration of extracorporeal support from hours to days, providing enough time for recovery of most neonates with respiratory failure. More recently, hollow fibre membrane oxygenators have been adapted for use, and both the oxygenator and the circuit can be heparin bonded.³⁹¹ As a result the requirement for heparin is reduced, which can be helpful in controlling bleeding. The technique is still of value only in the short term, but because myocardial dysfunction is likely to recover within 96 hours, this duration of support is suitable for the post-operative patient. Survival to discharge from hospital for patients who required extracorporeal support subsequent to the operation is in the range of 40%.^{392,393} Not surprisingly, among patients requiring such support, a lack of residual lesions favours survival.³⁹³ Patients with a functionally univentricular circulation suffering acute thrombosis of a shunt are noteworthy for a high rate of survival.³⁹³ Many centres have developed a rapid response system to permit rapid cannulation so as to salvage patients who sustained unexpected cardiac

arrest.³⁹⁴ The technique, however, is still suitable only for relatively short periods of treatment. The longest duration resulting in a hospital survivor without transplantation in a large series reported from the Children's Hospital of Philadelphia was 15 days. Bridging to transplantation requires long-term, low-morbidity support.

Providing mechanical support for the failing heart over longer periods has become a clinical reality in adults. Although the devices are imperfect, being subject to infection, haemolysis, and thromboembolic complications, long-term support has been possible. Patients have been bridged to transplantation with improvement in end-organ function, and reduction in pulmonary vascular resistance, ultimately resulting in a better candidate and a less complicated course following transplantation. The Heartmate and Thoratec devices, both manufactured by Thoratec (Pleasanton, CA) have been used in children. The Thoratec device in particular, an external or paracorporeal pump, has been used in patients as small as 17 kg.³⁹⁵

Devices are now available that are specifically designed for use in children. The DeBakey VAD Child (MicroMed Technology, Inc., Houston, TX) uses an axial flow pump, and is modified from a device designed for adults. The axial flow pump itself is identical to the one designed for adults, but the inflow and outflow cannulas and flow probe have been modified to accommodate smaller patients. This device was given exemption by the Food and Drug Administration for humanitarian use as a bridge to transplantation for children. It is totally implantable, and is approved for use in patients aged from 5 to 16 years, and with body surface areas greater than 0.7 m² and less than 1.5 m².^{396,397} The device has now been used in six patients with an average age of 11 years, and body surface areas from 0.8 to 1.7 m².³⁹⁸ The average duration of support was 39 days,

with 84 days being the longest duration of support. Half of the patients were successfully bridged to transplantation. There are three major shortcomings with the device. The smallest size available will ideally accommodate only larger children, limiting the application in smaller children. Additionally, the intracorporeal position complicates replacement if thrombus develops in the device. Furthermore, because it is an axial flow device, reverse flow, mimicking severe acute aortic insufficiency, may occur if the device stops, a condition that can occur with formation of thrombus.

The Berlin Heart (Berlin Heart AG, Berlin, Germany) is a paracorporeal pneumatic displacement pump. The pumping ventricle is available in a variety of sizes from 10 to 80 mL. The smallest size is suitable for support of infants.³⁹⁹ The experience in North America of May 2007 includes just under 100 patients. The longest duration of support is 234 days. Death occurred in one-quarter of those placed on the device, with just over half undergoing transplantation, and one-tenth being weaned from the device and a further one-tenth still being supported (personal communication). Because of the paracorporeal or external position of the pump, and the range of available cannulas, the device accommodates a range of anatomic variances. It is even possible to support patients with functionally univentricular circulations.⁴⁰⁰ Thrombus within the device can be identified by visual inspection, and the external position permits changing of the pump without reoperation.

Placement of any assist devices puts patients at risk for bleeding and thromboembolic complications. The risk appears to be greatest in the smallest patients. Presently both the DeBakey VAD Child and the Berlin Heart permit extubation and ambulation, both necessary conditions for rehabilitation (Fig. 13-14). Although the paracorporeal

Figure 13-14 A child being assisted with a Berlin Ventricular Assist Device. The child is fully ambulatory, and is able to leave his room under supervision.

pump may be more cumbersome, at present all devices in children are placed as bridges to transplantation, and not as permanent therapy. The ease of exchange of the pump, and the ability to accommodate anatomic variances and a greater range of size, favour the paracorporeal pump for use in children.

CONCLUSIONS

The beginning of cardiac surgery can be traced to the ligation of the persistently patent arterial duct, performed by Robert Gross in 1938, and reported in 1939. Cardiac surgery began, therefore, with the treatment of congenital cardiac disease. In the last 60 years, we have seen tremendous progress. Correction or palliation of congenitally malformed hearts is now routinely performed in infants and neonates, with the expectation of survival in most instances. Our goal in this chapter has been to review issues common to all congenital cardiac operations including incisions, materials used, conduct of cardiopulmonary bypass, and the options for extracorporeal support. We have sought to provide a balanced overview of the current state of the art, and perhaps included in our discussion the mean and first standard deviation of thought. The topic of surgical techniques is vast, and obviously beyond the scope of a single chapter. We believe we have provided a background, context, and a reasonable starting point for more thorough investigation.

ACKNOWLEDGEMENT

Acute Circulatory Failure: Pharmacological and Mechanical Support

LARA SHEKERDEMIAN

In 1913, Sir James MacKenzie, physician in charge of the cardiac department at the London Hospital, defined cardiac failure as a condition in which 'the heart is unable to maintain an efficient circulation when called upon to meet the efforts necessary to the daily life of the individual'. The causes of such circulatory failure in children include sepsis, primary myocardial disease such as myocarditis or cardiomyopathy producing end-stage failure with acute decompensation, and congenital cardiac disease. Children with congenitally malformed hearts suffering circulatory failure can present in the unoperated state, or in the early post-operative period after surgery, when the condition is usually recoverable. Myocardial performance in children with acute circulatory failure depends upon the underlying condition, and in some cases may change with time. The unifying feature for all children with acute circulatory failure is that the heart is unable to meet the circulatory demands of the tissues. Treatment, therefore, must be directed at restoring this critical balance.

Over the past decade, there have been important advances in the approach to the treatment of acute cardiac failure. Treatment has shifted away from a focus on myocardial contractility in favour of strategies which optimise systemic perfusion, protecting the myocardium through manipulation of afterload, control of the demand for oxygen, or in the extreme by providing complete myocardial rest.

The successful management of children with acute cardiac failure depends upon providing careful and individualised treatment, which begins with establishing the underlying cause, with subsequent tailoring of available treatments. In this chapter, I begin with a broad overview of the pathophysiology of circulatory failure in children. I then discuss the spectrum of available therapies for acute circulatory failure, focusing on pharmacological agents, and non-pharmacological treatments, considering both extracorporeal support and ventilation. The principles of good, basic intensive care, and the application of understanding of the complex circulatory physiology of children with cardiac disease, will complement all of the ensuing discussions, as these are prerequisites for successful therapy.

THE PATHOPHYSIOLOGY OF ACUTE CIRCULATORY FAILURE

Acute circulatory failure in children with cardiac disease can be classified into five broad categories, according to intrinsic cardiac function, global cardiac output, and overall balance of oxygen. These categories differ significantly

in their manifestations, underlying causes, and subsequent therapeutic strategies, but share a common feature, which is the phenomenon of systemic hypoperfusion.

- **Acute myocardial dysfunction with reduced cardiac output and increased afterload.** Acute myocardial dysfunction with reduced systemic delivery of oxygen characterises the low cardiac output which complicates the post-operative course of around one in four children early after cardiopulmonary bypass. A fundamental feature of this is an elevated ventricular afterload, abnormal ventriculo-vascular interactions, as well as impaired systolic and/or diastolic function. This is the most commonly encountered cause of acute circulatory failure in children with cardiac disease.
- **Preserved myocardial function with normal cardiac output but systemic hypoperfusion.** Inadequate systemic delivery of oxygen can affect infants with a functionally univentricular heart and good ventricular contractility whose total cardiac output may be normal, but is maldistributed between the pulmonary and the systemic circulations. These infants are very dependent upon the maintenance of stable pulmonary and systemic vascular resistances, and even small changes in these can precipitate rapid circulatory failure and systemic hypoperfusion.
- **Preserved systolic function with abnormalities of diastolic function.** A proportion of patients with normal systolic function after surgical repair of tetralogy of Fallot, or conversion to the Fontan circulation, can develop a low cardiac output early after surgery which is secondary to diastolic dysfunction and inadequate flow of blood to the lungs. In these patients, treatment is directed at optimising diastolic function and cardiopulmonary interactions, while avoiding interventions which increase contractility.
- **Residual anatomic lesions in post-operative patients.** In a minority of patients after cardiac surgery, a low cardiac output state may be secondary to residual anatomic problems. In the absence of targeted investigations, these are often clinically indistinguishable from other causes of a low output, but are generally resistant to, or paradoxically may be worsened by, conventional medical interventions.
- **Preserved myocardial function with normal or increased cardiac output.** Inadequate systemic delivery of oxygen in the presence of normal myocardial function, reduced afterload, and normal or increased cardiac output, is an important, though unusual cause of acute

Figure 14-1 Junctional ectopic tachycardia may be clinically indistinguishable from other causes of a low cardiac output early after cardiac surgery. Escalation of inotropes may exacerbate the arrhythmia, hence the importance of diagnostic investigations. Appropriate therapy includes measures to slow the rate, such as hypothermia or amiodarone, and pacing.

circulatory failure. In this setting, despite a seemingly normal cardiac output, the total or regional demand for oxygen is excessively high. This occurs in children with sepsis, or the systemic inflammatory response syndrome. Deceptively, the prodrome of acute myocarditis may also present in this way, but this so-called honeymoon period generally precedes a rapid circulatory collapse.

The first four categories described above generally affect infants and children with congenitally malformed hearts who are undergoing cardiac surgery. We can surmise, therefore, that circulatory failure in many infants and children with heart disease is to an extent predictable. In these patients, therefore, medical management should routinely include proactive strategies which are targeted at the prevention of this phenomenon. If circulatory failure does occur, then this should prompt early investigation and subsequent therapeutic intervention with appropriate measures.

A FRAMEWORK FOR THE MANAGEMENT OF ACUTE CIRCULATORY FAILURE IN CHILDREN

Acute cardiac failure in adults is often unexpected, whereas this condition is often predictable in many children with pre-existing cardiac disease. This unusual paradox presents a great opportunity for pre-emptive management in children who are undergoing surgery for congenitally malformed hearts, with the appropriate tailoring of post-operative management. Where anticipatory therapy is not possible, for example in acute myocarditis, or in circumstances where this does not prevent circulatory failure, then a proactive approach with early investigation, consideration of therapeutic targets, and appropriate intervention is recommended.

The Importance of Detailed Investigation

Although circulatory failure may be predictable in some settings, such as the post-operative period after cardiopulmonary bypass, it is unwise simply to accept its onset without considering early reinvestigation to guide therapy or to rule out a treatable cause. In children with circulatory instability early after cardiac surgery, echocardiography can immediately differentiate systolic and diastolic dysfunction, or may reveal an unexpected, acutely treatable cause

such as a pericardial effusion. Similarly, detailed electrocardiography and atrial electrograms may demonstrate a treatable arrhythmia as the cause (Fig. 14-1). Moreover, echocardiography or additional imaging with cardiac catheterisation or computerised tomographic angiography may confirm or exclude anatomic causes for circulatory failure, such as collateral circulations, residual intracardiac shunting, or obstruction in the pulmonary or systemic circulations (Fig. 14-2).

Circulatory failure in post-operative cardiac patients can be due to different causes, which may be clinically indistinguishable, but which require very different treatments. Timely investigations, therefore, avoid the inappropriate use of therapies which may further exacerbate the underlying problem or its clinical manifestation. This is particularly relevant when circulatory failure is related to a tachyarrhythmia such as junctional ectopic tachycardia,

Figure 14-2 Aorto-pulmonary collateral arteries can contribute to a state of low output after surgery for congenital cardiac disease. The aortogram shows such major collateral vessels (arrows) in an infant with a low cardiac output, and well-preserved systolic and diastolic function after surgical repair of tetralogy of Fallot.

an undiagnosed anatomic outflow obstruction or pure diastolic dysfunction. In these situations, which may all be clinically indistinguishable from systolic myocardial dysfunction, escalating inotropic therapy generally will further potentiate the haemodynamic instability. Having highlighted the importance of diagnosing or excluding treatable causes for circulatory failure, as part of a pragmatic approach to management, we must next focus upon current therapies for primary circulatory failure.

Therapeutic Targets

The basic premise for the management of acute circulatory failure is to restore the systemic balance of oxygen, by manipulating one or more of the following:

- Systolic function
- Diastolic function
- Preload
- Afterload
- Consumption of oxygen
- Cardiopulmonary interactions

This is most often achieved using one or more of the therapeutic tools listed below.

Therapeutic Tools

A variety of tools are available for the treatment of acute circulatory failure in children. Those which will be discussed in further detail are:

- Ventilation to optimise cardiopulmonary interactions
- Pharmacological agents to improve contractility and loading conditions
- Mechanical support, such as extracorporeal membrane oxygenation, or use of devices providing temporary ventricular assistance to optimise cardiac output while allowing myocardial rest.

In the remainder of this chapter, I will discuss how these essential haemodynamic tools can be applied to infants and children with circulatory failure in the intensive care unit.

THERAPIES FOR CIRCULATORY FAILURE IN CHILDREN

Ventilation

In this section, I discuss the application of one of our most basic haemodynamic tools, namely ventilation, in relation to children with cardiac disease. In addition to its primary function, which is to maintain gas exchange, ventilation is an important haemodynamic tool in children with cardiac disease, and should routinely be used to optimise the systemic perfusion. Cardiopulmonary interactions describe the interplay between spontaneous or mechanical ventilation and the cardiovascular system. These interactions differ greatly in health and disease, and unique interactions are present in children with congenitally malformed hearts.

The application of mechanical ventilation in children with circulatory failure requires an understanding of the underlying diagnosis and physiology, and of how cardiopulmonary interactions may therefore be tailored for an individual. Similar to inotropes, an approach which may benefit one patient may be highly detrimental to another,

which highlights the importance of understanding the underlying pathophysiology.

Cardiopulmonary Interactions: Ventilation and the Cardiovascular System

The modern understanding of cardiopulmonary interactions has largely followed pioneering work from Cournaud and his co-workers in the mid-1900s.¹ This group carried out a number of fundamental investigations, which addressed many aspects of the complex relationship between spontaneous and mechanical respiration and the cardiovascular system. They showed that, in the healthy circulation, the fall in intrathoracic pressure during spontaneous inspiration was associated with an increase in cardiac output secondary to increased right ventricular preload. Conversely, positive pressure ventilation produced a reduction in venous return and right heart filling, resulting in a small reduction in cardiac output which was proportional to the mean airway pressure (Fig. 14-3).

The effects of ventilation are not confined to its influences on the preload of the right heart. Positive pressure ventilation can also impede the emptying of the right heart through its effects on pulmonary vascular resistance, and may also reduce left ventricular afterload through a reduction in transmural left ventricular pressure.² These haemodynamic effects are, in practice, of minimal importance in the healthy individual. In the presence of circulatory failure, or in patients at risk for this, cardiopulmonary interactions become much more relevant in both the genesis of the problem, and in its treatment.

Cardiopulmonary Interactions in Children with Systolic Ventricular Dysfunction

In an historic study in 1973, it was shown that some adults with systolic ventricular dysfunction following open heart surgery responded to separation from positive pressure ventilation with an unexpected fall in cardiac output which was not associated with any disturbance in gas exchange.³ Positive pressure ventilation reduces the work of breathing, filling of the right heart, and left ventricular transmural pressure, resulting in reduced left ventricular afterload. These cardiopulmonary interactions may be very desirable in patients with impaired systolic ventricular function, and are obviously lost on extubation from positive pressure ventilation. Similar haemodynamic effects also contribute to the improved early outcomes of adults presenting with acute, decompensated cardiac failure who are treated with non-invasive positive pressure ventilation.⁴

Positive pressure ventilation should therefore routinely be considered as a form of haemodynamic support for young infants with systolic impairment early after cardiac surgical repair. Common post-operative examples where infants may benefit from the reduction in right ventricular preload, left ventricular afterload and work of breathing afforded by positive pressure ventilation include the arterial switch operation, reimplantation of an anomalous left coronary artery from the pulmonary trunk or relief of left ventricular obstruction. These infants, and others with significant cardiac dysfunction may also benefit from a period of continuous positive airways pressure as ongoing haemodynamic support following extubation. Children with acute myocardial dysfunction secondary to sepsis or

Figure 14-3 The influence of airway pressure on the cardiac output of healthy individuals. In their landmark research, Courmand and colleagues established that the reduction in cardiac output (CO) during positive pressure ventilation, was due to the effects of airway pressure on right heart filling. The graphs shown here, based on those of Courmand and colleagues,¹ show that the change in cardiac output is related to airway pressure, such that a higher mean airway pressure and longer inspiratory time (A and B) produces a significant fall in cardiac output. A low airway pressure, with a short inspiratory time (C), does not adversely affect cardiac output.

myocarditis may similarly benefit from positive pressure ventilation, through either an endotracheal tube or via the non-invasive route.

Cardiopulmonary Interactions in Children with Abnormalities of Diastolic Function

Infants and children with diastolic impairment associated with congenital cardiac disease respond very differently to mechanical ventilation, and this highlights, once again, the importance of anticipating or diagnosing the problem, and tailoring therapy according to the underlying physiology. A low cardiac output in the presence of normal systolic ventricular function can complicate the early post-operative period of infants and children after surgery on the right heart, specifically after repair of tetralogy of Fallot, or establishment of the Fontan circulation. Although the anatomies of these entities are very different, their cardiopulmonary physiology in the early post-operative phase is in fact very similar.

The cardiac output of patients with the Fontan circulation is critically dependent upon the pulmonary vasculature. Consequently, the low cardiac output in these patients is most often related to inadequate flow of blood to the lungs, rather than problems with systolic ventricular function. In the absence of a subpulmonary ventricle, these patients depend upon the fall in intrathoracic pressure during spontaneous respiration in order to maintain flow to the lungs. Conversely, a positive intrathoracic pressure can impede or even reverse such flow.⁵ Indeed, in his original description of his operation, Fontan observed the clinical improvement that accompanied extubation, and recommended that spontaneous respiration be established early after surgery.⁶

A subgroup of patients early after repair of tetralogy of Fallot have a reduced cardiac output secondary to restrictive right ventricular physiology, and their cardiac output is very dependent upon diastolic forward flow to the pulmonary arteries. Of key importance for the intensive care of these patients, as for those with the Fontan circulation, is that their pulmonary flow is critically related to intrathoracic

pressure. In children with restrictive physiology, increases in airway pressure reduce or completely obliterate the diastolic pulmonary flow, which is an important source of cardiac output. Conversely, by mimicking spontaneous respiration, negative pressure ventilation augments cardiac output.⁷

Thus, children with the Fontan circulation, and a subgroup of patients early after repair of tetralogy of Fallot, share some fundamental, and quite unique cardiopulmonary interactions in the early post-operative period. In these patients, inappropriate ventilatory management using principles applied to children with systolic dysfunction could exacerbate clinical instability. The pre-emptive or early proactive circulatory management should include the use of low ventilatory pressures, and early extubation where possible.

Cardiopulmonary Interactions in the Functionally Univentricular Circulation

Ventilation is a very simple, and fundamental tool which can, and should, be used to manipulate the perfusion of young infants with a functionally univentricular circulation. Similar principles can be applied to infants with hypoplastic left heart syndrome and its variants before or after surgery, to infants with a common arterial trunk in the pre-operative setting, and to neonates early after a systemic-to-pulmonary shunt. The maintenance of a stable pulmonary resistance is key to the early optimisation of these infants, and this is greatly influenced by ventilation. Seemingly minor increases in pulmonary blood flow secondary to alkalosis, or excess inspired oxygen, can compromise systemic flow. A time of particularly high risk is immediately after birth, when there may be a temptation to resuscitate these infants with oxygen, or hyperventilation. Even minimal periods of supplemental oxygen can be highly detrimental to these infants, and can precipitate metabolic acidosis, shock and circulatory collapse. This is an important factor which differentiates the resuscitation of infants with a prenatal diagnosis, from those without, in whom supplemental oxygen is more likely to be administered. The outcome of

these infants is in part associated with their worst acid-base state, which is critically related to ventilatory management, and is influenced by the timing of diagnosis.⁸

In infants with a functionally univentricular circulation who are haemodynamically unstable in the pre-operative period, conservative levels of positive pressure ventilation can be used to control pulmonary flow. Ventilation using high airway pressures, or slow rates, is no longer used deliberately to induce respiratory acidosis and pulmonary vasoconstriction, as acidosis is not advantageous to these infants. Instead, mechanical ventilation stabilises the pulmonary resistance, and in turn this helps to optimise the systemic perfusion.

The use of supplemental nitrogen or carbon dioxide, delivered with the ventilatory gases, to augment the systemic perfusion before or after Norwood-type operations, has also been investigated. There is limited data which suggest that, while the addition of nitrogen to achieve an inspired oxygen fraction of around 0.17 lowers the systemic arterial saturations, it also reduces the mixed venous saturation and cerebral delivery of oxygen. In contrast, the addition of 3% carbon dioxide to the ventilatory circuit improves mixed venous saturation and cerebral saturation without changing the systemic arterial saturation, suggesting that this manoeuvre does improve the systemic delivery of oxygen in high risk infants.^{9,10}

Summary of Ventilation as a Haemodynamic Tool

Children with cardiac disease have complex, and varied, cardiopulmonary interactions, which depend upon the underlying diagnosis, type of surgery, and associated myocardial function. Ventilation should routinely be tailored

to manipulate haemodynamic performance, and may often be of more benefit to the child than pharmacotherapy (Table 14-1).

Cardiovascular Drugs

In recent years, the approach to pharmacological therapy for acute circulatory failure has moved away from the historical premise that the default target for treatment should be myocardial contractility. A better understanding of the pathophysiology and haemodynamic manifestations of circulatory failure in children has resulted in a shift away from therapy using pure inotropes to measures which also focus on the peripheral vasculature, and the interactions between the periphery and the myocardium. Current approaches are aimed at optimising afterload and manipulating contractility with careful, not excessive, inotropic therapy, while avoiding any unwanted increases in vascular resistance or myocardial oxygen consumption.

Drug therapies for acute circulatory failure are generally categorised according to their pharmacological actions, and also by their physiological effects. The classes of drugs most commonly used to treat acute circulatory failure in children are catecholamines and phosphodiesterase inhibitors. More recently, a number of newer drugs which influence cardiovascular function through very different mechanisms including sensitisation to calcium, and neurohormonal effects, have also become available for clinical use. The physiological effects of drugs used to treat cardiac failure are inotropic, vasodilator or a combination of the two, the so-called inodilator effect.

TABLE 14-1

SUMMARY OF THE HAEMODYNAMIC EFFECTS OF SPONTANEOUS AND MECHANICAL VENTILATION IN CHILDREN WITH HEART DISEASE

Nature of Cardiac Failure	Key Considerations	SPONTANEOUS RESPIRATION		POSITIVE PRESSURE VENTILATION/CPAP	
		Cardiopulmonary Features	Haemodynamic Effect	Cardiopulmonary Features	Haemodynamic Effect
Systolic cardiac failure (post-op, myocarditis)	Increased LV afterload Systolic LV dysfunction	Increased work of breathing Exaggerated negative intrapleural pressure	Increased LV afterload Jeopardises the systemic perfusion	Reduced work of breathing Obliterates negative swings in pleural pressure	Reduced venous return Reduced LV afterload Improved LV function
Post-op tetralogy of Fallot	Good systolic function Diastolic RV dysfunction Preload dependent	Increased RV preload Improved diastolic pulmonary artery flow	Improved cardiac output	Reduced RV preload Reduced diastolic pulmonary artery flow	Reduced cardiac output
Post-op Fontan	Good systolic function Preload dependent Cardiac output depends on pulmonary blood flow	Increased preload	Improved pulmonary flow and cardiac output	Reduced preload Reduced pulmonary blood flow	Reduced cardiac output
Duct-dependent systemic flow	Excessive pulmonary flow leading to reduced systemic flow Control difficult if infant is spontaneously breathing	Respiratory alkalosis and oversaturation often associated with low pulmonary vascular resistance	May result in excessive pulmonary flow, reduced systemic perfusion	Better control of pulmonary flow, pH, and pulmonary resistance	Improved systemic cardiac output

CPAP, continuous positive airway pressure; LV, left ventricular; RV, right ventricular.

Special Considerations in Children

When approaching pharmacological treatment of cardiac failure in infants and children, it is important first to consider some unique factors affecting children, which influence the choice of therapy in specific situations.

Maturational Influences

The neonatal myocardium differs significantly from the more mature heart in its innervation, and contractile reserve. The neonatal heart is less densely supplied with sympathetic nerve terminals than older infants and adults, which results in reduced myocardial effects, and less re-uptake of catecholamines. This latter factor may also predispose to the cardiotoxicity of catecholamines which has been described in the neonatal myocardium.¹¹ The newborn myocardium is, conversely, more sensitive to changes in intracellular calcium such that agents which act upon this may be of greater utility.

The Pulmonary Vasculature

Pulmonary hypertension, or lability of the pulmonary vascular resistance, is commonly encountered in newborns and infants with cardiac disease, and changes in pulmonary vascular tone can play a role in the genesis of circulatory failure in some patients. Patients at increased risk of pulmonary hypertension include those with structural heart disease resulting in excessive pulmonary blood flow, pulmonary venous hypertension or a functionally univentricular circulation. Pulmonary vascular instability can be further compounded in the newborn transitional circulation, and by cardiac surgery and cardiopulmonary bypass which disturbs the balance between endogenous pulmonary vasodilators and constrictors.^{12,13}

Complex Circulations

Careful control of vascular tone is a pre-requisite for the circulatory management of patients with more complex congenitally malformed hearts, in particular those with a functionally univentricular heart. In these patients, acute changes in pulmonary or systemic vascular resistance can immediately impact on the systemic delivery of oxygen, and can rapidly precipitate acute circulatory failure. In these patients, stable pulmonary vascular resistance, and an appropriately dilated systemic vasculature is highly desirable.^{14,15}

The presence of severe congenital cardiac disease can also impact on the responsiveness of the heart to exogenous agents. Sympathetic dysregulation is most marked in newborns and young infants with cyanotic or critical acyanotic cardiac disease. In these infants, a reduced density of β -adrenoreceptors is associated with elevated endogenous levels of noradrenaline and a partial uncoupling of the receptor to adenylate cyclase. As a result the myocardium is less responsive to β -adrenergic stimulation.¹⁶

Catecholamines

Adrenaline, noradrenaline and dopamine are endogenous neurotransmitters that play a central role in the physiological response to physiological stressors including hypoxia, hypotension, hypovolaemia, acidosis, temperature, and pain. Exogenous catecholamines are commonly administered to infants and children with circulatory failure, or to those who are at risk for this.

Catecholamine Receptors

Catecholamines produce their clinical effects through their interaction with post-synaptic α - and β -adrenergic receptors, and dopaminergic receptors, which are located on the myocardium, and on the peripheral vasculature.

The α_1 -, α_2 -, and β -adrenoreceptors were originally characterised by Ahlquist in 1948. Each is known to have at least three sub-types. The physiological effects of catecholamine receptor stimulation are produced through alterations in intracellular ionised calcium.

Physiological Effects of Individual Receptor Stimulation

Stimulation of α_1 -receptors leads to increased influx of calcium to the post-synaptic effector cell, resulting in peripheral vasoconstriction; α_2 - and β -adrenergic agonists bind to their respective G-protein coupled adrenoreceptors, and activate adenylate cyclase which increases intracellular cyclic-adenosine monophosphate. This produces increased contractility, heart rate, and vasodilation. Dopamine receptors are located on tissues and the peripheral vasculature. They are classified into two categories according to their structure and actions. These receptors are generally referred to as dopamine₁-like, specifically dopamine₁ and dopamine₅ subtypes, and dopamine₂-like, comprising dopamine_{2/3} and dopamine₄ subtypes.¹⁷⁻¹⁹ Stimulation of dopamine receptors results in vasorelaxation through two potential mechanisms. Stimulation of dopamine₁-like receptors reduces the sensitivity of the post-synaptic cell to intracellular calcium.²⁰ Stimulation of dopamine₂-like receptors, in contrast, inhibits release of noradrenaline from the nerve terminal.²¹

Pattern of Receptor Stimulation by Individual

Catecholamines

Adrenaline. Adrenaline is an α - and β -agonist, which at lower doses theoretically produces predominantly β -effects, such as increased heart rate and contractility, with some reduction in peripheral resistance, and an increase in cardiac output. At higher doses, adrenaline stimulates α -receptors and increases vascular resistance, with a concomitant increase in myocardial demand for oxygen. Although the effects are in theory dose-related, in practice the degree of relative β - versus α -effects in response to adrenaline is unpredictable, and systemic vasoconstriction is common.

Noradrenaline. Noradrenaline predominantly stimulates α -receptors, resulting in systemic vasoconstriction, without directly influencing cardiac output. This may be desirable in the presence of excessive vasodilation, but can potentially worsen the cardiovascular performance in patients with elevated ventricular afterload and borderline ventricular function.

Dopamine. Dopamine was identified as an endogenous neurotransmitter in 1958,²² and was subsequently shown to have pressor effects,^{23,24} and direct cardiac effects.²⁵ Dopamine stimulates α , β , and dopamine receptors, and produces an array of physiological responses with vasodilation secondary to dopaminergic stimulation, and α - and β -adrenergic stimulation at higher doses. The theoretical dose-related spectrum of effects led to the labels of renal and cardiac doses being applied for lower and higher doses, respectively. This concept is now obsolete, as there is no evidence to support such specific dose-selective actions.²⁶ Thus, the physiological effects seen when dopamine is administered are increases in contractility, heart rate, and vascular tone, with little if any convincing evidence of systemic vasodilation.

Dobutamine. Dobutamine was originally developed as a selectively inotropic catecholamine for adults with circulatory failure.²⁷ The drug has primarily β -adrenergic effects, with increased contractility and peripheral vasodilation, accompanied by a modest increase in heart rate.²⁸ It also improves myocardial flow, which balances adverse effects

on consumption of oxygen brought about by the chronotropic response.²⁹

Caveats with the Administration of Catecholamines

The clinical response to catecholamines is often less clear-cut or predictable than might be hoped. This is, in part, related to the highly variable dose-response relationship which has already been described. It is also due to the intrinsic property of most agents to produce multiple physiological effects, and due to unique factors present in children.

Unpredictable Pattern of Catecholamine Receptor Stimulation. Catecholamines have multiple physiological effects, and the overall efficacy of a single agent relies on any undesirable effects being counter-balanced by beneficial effects. For example, if the chronotropic response to adrenaline or dopamine, which may result in increased myocardial consumption of oxygen, to adrenaline or dopamine is not met with an appropriate increase in myocardial flow, then myocardial ischaemia may result. Moreover, a single catecholamine may stimulate more than one receptor, which could produce exactly opposing effects. For example, exogenous dopamine may concomitantly produce α -mediated vasoconstriction and dopaminergic vasodilation. A desired effect can also prove detrimental if endogenous cardiovascular compensation is not achieved. The administration of noradrenaline can produce peripheral vasoconstriction. The resulting increase in ventricular afterload may need to be met by an increase in contractility, and if this cannot be achieved through endogenous compensation, the net result is worsening of the cardiac output.

Factors Related to the Patient. Downregulation of catecholamine receptors due to elevated endogenous levels is well-recognised in critically ill infants and children with cardiac disease. Specific circumstances include patients who have received exogenous catecholamines for prolonged periods, those with cardiac disease and overwhelming circulatory failure, and children who have recently undergone cardiopulmonary bypass.^{30,31}

Clinical Application of Catecholamines in Children

Despite the factors which are listed above, catecholamines remain the first line therapy for acute circulatory failure in children. This is undoubtedly related to familiarity with these drugs and our ability to work around aspects of their inherent unpredictability, features which are somewhat off-set by their rapid onset of action and short half-life.^{32,33} In addition catecholamines are widely available and relatively cheap.

Clinical Trials Comparing Effects of Catecholamines

A number of randomised studies in adults have suggested that, as a single agent, dobutamine is superior to dopamine in its haemodynamic effects in post-cardiac surgical patients,³⁴ after major surgery,³⁵ and in the setting of septic shock.³⁶ There are few clinical trials comparing the haemodynamic effects of catecholamines in paediatric cardiac intensive care, and none which focus on objective outcome measures. In children with cardiac disease, it is extremely important to consider not only cardiac output as a marker of the haemodynamic efficacy of a catecholamine, but equally to consider its influence on other vascular beds. While dopamine and dobutamine both improve the global cardiac output in infants and children after cardiac surgery,^{37,38} dopamine, and not dobutamine, increases pulmonary vascular resistance in these patients.³⁹ In a model of right ventricular injury and pulmonary hypertension, dopamine, dobutamine and adrenaline all produced

similar improvements in right ventricular function. Dobutamine and adrenaline, but not dopamine, reduced the pulmonary vascular impedance, and adrenaline was the only agent which improved overall pulmonary vascular and right ventricular coupling.⁴⁰

Adrenaline

Adrenaline is generally administered as an inotropic agent in patients with poor myocardial function, for example early after cardiac surgery. Even at the lowest doses, systemic vasoconstriction may complicate the administration of adrenaline, and this can exacerbate the elevated ventricular afterload which is characteristically common in the early post-operative period. In order to overcome unwanted systemic vasoconstriction, consideration should be given to the concomitant, and careful, addition of a short-acting intravenous nitro-vasodilator.

Noradrenaline

Noradrenaline should be used carefully as a single agent in cardiac intensive care, as it generally increases the systemic vascular resistance without any compensatory enhancement of cardiovascular performance. It may, therefore, exacerbate a low cardiac output in patients with minimal myocardial reserve and borderline ventricular function. When used in low doses, nonetheless, it is useful for patients with circulatory failure secondary to a post-operative systemic inflammatory response. Noradrenaline can be used either alone, or in combination with careful inotropic support, to improve pulmonary perfusion in patients where this is critically reduced, or coronary arterial perfusion in patients with diastolic run-off. Examples are patients with a borderline cardiac output but good ventricular function after conversion to the Fontan circulation, young infants after construction of a systemic-to-pulmonary arterial shunt, or infants with a critically obstructed pulmonary circulation prior to any surgical relief.

Dopamine

The systemic and pulmonary vasoconstriction which often accompanies the administration of dopamine somewhat negates its desirable inotropic effects, and renders the agent less useful as a single agent for infants and children with circulatory failure. This can, in part, be mitigated by combining dopamine with a systemic vasodilator. Dopamine, nonetheless, is uncommonly used in paediatric cardiac intensive care.

Dobutamine

Dobutamine is arguably the most commonly used single agent for the treatment of acute circulatory failure in all age groups. The appeal of dobutamine as a single agent arises from the combination of its inotropic effects with systemic and coronary vasodilation, which unlike other catecholamines co-exist at a single dose. These properties underpin its popularity in infants and children weaning from cardiopulmonary bypass, and in the initial treatment of primary myocardial failure.

Phosphodiesterase Inhibitors

These agents are classed as inodilators, being agents with both inotropic and vasodilator properties.

The Biology of Phosphodiesterase Inhibitors

Phosphodiesterase inhibitors are derivatives of bypridine. They prevent the intracellular hydrolysis of 3'5' cyclic adenosine monophosphate by the enzyme phosphodiesterase III, which is plentiful in the myocardium and vascular smooth muscle cells. There are three such inhibitors,

namely amrinone, enoximone, and milrinone. Their pharmacological effects are mediated through an increase in intracellular cyclic adenosine monophosphate, which has been shown to result in peripheral and coronary vasodilation, increased myocardial contractility, and improved myocardial relaxation.^{41–43} In theory, therefore, they are inodilators with additional lusitropic, or diastolic relaxant, effects.

Milrinone

Milrinone is the phosphodiesterase inhibitor which is most widely used at present. It improves cardiovascular performance through systemic vasodilation, and has additional pulmonary vasodilator properties, which may be particularly desirable in young infants at risk of post-operative pulmonary hypertension.⁴⁴ It is now very frequently used in paediatric cardiac intensive care as a short-term infusion, and its most common use is in the early period after cardiopulmonary bypass, where its prophylactic use has been shown to prevent the onset of a low cardiac output in patients already receiving intravenous catecholamines.⁴⁵

Most clinicians readily refer to milrinone as an *inodilator*. There is no question that milrinone is a potent vasodilator. It is unclear whether the clinical improvement, or maintenance, of haemodynamic stability in children receiving milrinone may simply be through a reduction in afterload alone, or whether this is also attributable to its inotropic and lusitropic properties. In order to investigate this, a comparison of the haemodynamic effects of milrinone with a pure vasodilator would be necessary.

Pharmacology of Milrinone

Milrinone has a more complex pharmacokinetic profile than catecholamines. It has a slower onset of action, a much longer half-life, around 3 hours, and is excreted unchanged by the kidney. In order to achieve its maximum efficacy in a timely manner, milrinone must be administered as a loading dose followed by a continuous infusion. The dose administered should be adjusted according to both age, and renal function.^{46,47} The clinical effects are generally evident for between 6 and 24 hours after discontinuing the infusion, and this important observation should influence the timing of initiating oral vasodilator therapy.

Caveats with Administration

An important consideration when administering milrinone is that the vasodilation, and the reduction in filling pressures which accompany its initial use may be substantial. This is particularly significant following cardiopulmonary bypass and ultrafiltration, when the patient is often hypovolaemic. To this end, a bolus of colloid should be available to militate against this effect during the early phase of administration. In general, its overall beneficial effects outweigh this temporary and avoidable phenomenon.

A more important consideration with all phosphodiesterase inhibitors is the confidence with which a vasodilator with a long duration of action can, or should, be administered to a given patient. For example, the use of milrinone as the first-line agent in patients with any potential for fixed cardiac outlet obstruction would not be recommended, as the fall in preload and afterload may impair subsequent systemic and/or pulmonary perfusion. In these circumstances, the initial use of a vasodilator with a short half-life, such as a nitro-vasodilator, would be advisable in order to ascertain whether vasodilation will be tolerated.

Clinical Uses of Milrinone

Milrinone is a useful agent for infants and children who have, or who are at risk of developing acute cardiac failure secondary to ventricular dysfunction, for example children immediately after cardiac surgery in whom there is no obstruction to the ventricular outlets. In this setting, milrinone can be used as a single agent, or as an adjunct to an inotropic catecholamine. Milrinone may also be useful in children who are at additional risk of developing circulatory failure secondary to post-operative pulmonary hypertension, for example after closure of a large intracardiac shunt, or after early neonatal reparative surgery. Additional clinical uses include patients with severe myocardial dysfunction which is unrelated to cardiac surgery, for example children with an acute decompensation of chronic cardiac failure.

Newer Vasoactive Agents

Sensitisers to Calcium

The role of calcium in cardiovascular regulation has been alluded to in this chapter and elsewhere. It is clear that the majority of cardiogenic drugs exert their haemodynamic effects either directly or indirectly through their influence on intracellular calcium. Most inotropes increase contractility through changing concentrations of ionised calcium within the cytoplasm or sarcoplasmic reticulum of the cardiomyocyte. An additional mechanism of action of cardiovascular agents has recently been established, which is to increase the sensitivity of the contractile apparatus to calcium without altering its total intracellular concentration.⁴⁸ Levosimendan was the first such agent to enter clinical practice, and has gained great popularity in the treatment of adults with circulatory failure.

Biology of Levosimendan

Levosimendan increases myocardial contractility through sensitisation to calcium. Levosimendan also produces coronary and peripheral vasodilation by opening the adenosine triphosphate-dependent potassium channels within the mitochondria of vascular smooth muscle.⁴⁹ Levosimendan, therefore, has very different molecular actions to those of all the drugs so far discussed, and all of these properties would make it a very appealing drug as the primary, adjunctive, or secondary therapy for children with acute circulatory failure.

Levosimendan has been widely investigated in a number of models of cardiovascular dysfunction, and is known to improve global haemodynamics and left and right ventricular systolic function, without increasing the myocardial demand for oxygen. Its effects, however, are not confined to myocardial contractility, and the agent also has been shown to optimise right and left ventriculo-vascular coupling, along with systemic and pulmonary vascular resistances, in laboratory models of myocardial injury.^{50,51}

Pharmacology and Administration of Levosimendan

The concept of treating acute circulatory failure with long-acting vasoactive drugs has already been introduced. Levosimendan has much longer duration of clinical effects than milrinone, and its pharmacokinetics have dictated its unusual dosing regime. It has at least two active metabolites, which both have prolonged effects.⁵² The current recommended dose regime for levosimendan in adults is for a bolus dose to be followed by an infusion for 24 hours. Thus, a single infusion of levosimendan produces haemodynamic effects which last for between 4 and 7 days. The unique pharmacokinetics of levosimendan result in the

potential for its use in a cyclic manner, or potentially rotating with intermittent catecholamine administration.

Clinical Application of Levosimendan

Levosimendan has been widely investigated in adults with acute decompensated cardiac failure, and early experience suggested improved survival in these patients when compared with dobutamine.⁵³ This observation, however, was not borne out in the more recent SURVIVE study.⁵⁴ Levosimendan has also been shown to improve right ventricular performance in patients with acute lung injury,⁵⁵ and regional perfusion in patients with septic myocardial dysfunction.⁵⁶ In combination with dobutamine, levosimendan appears to have superior haemodynamic effects, and improves early outcome compared with milrinone in high risk adults after cardiac surgery.⁵⁷

Levosimendan would appear to be a very appealing agent for use in infants and children requiring continued cardiovascular support, in whom prolonged treatment with catecholamines is likely to be met with tachyphylaxis. In these patients, the administration of a single dose of levosimendan should enable the discontinuation of catecholamines, with their reintroduction several days later, by which time receptor-responsiveness is likely to have been regained. This approach has been shown to improve survival when compared with a single dose of catecholamine in adults with severe cardiac failure.⁵⁸

Levosimendan in Children

The experience with levosimendan in children is currently very limited. We have recently reported improved ejection fraction and reduced catecholamine requirements in children with severe cardiac failure who were given levosimendan (Fig. 14-4).⁵⁹ Its role in children early after cardiac surgery has not been established, though the agent shows great promise in this area. In a laboratory comparison of levosimendan and milrinone in a model of infant cardiac surgery, we have recently shown that the two agents have equivalent effects on afterload and ventricular-vascular coupling, but levosimendan has superior effects on contractility.⁵¹ The drug, therefore, is an inodilator which shows great potential for infants and children with cardiac failure, but which warrants much more detailed investigation in this population.

Natriuretic Peptides

Atrial natriuretic peptides with potent natriuretic, diuretic, and vasodilatory properties were first identified from mammalian atrial tissue in the early 1980s.⁶⁰ In 1988, a molecule with similar properties was identified from brain tissue, and this was named brain natriuretic peptide, though its primary site of synthesis was subsequently shown to be the ventricle of the heart.⁶¹ Brain natriuretic peptide is released from the ventricle in response to distension in patients with cardiac failure. It has been widely researched as a biomarker of severity of cardiac failure, prognostic indicator, or marker of response to therapy in a number of settings. Nesiritide, a recombinant brain natriuretic peptide, has been widely investigated as a vasodilator for the treatment of acute cardiac failure in adults.

The Biology of Nesiritide

Nesiritide is a pure vasodilator without any actual or theoretical inotropic properties. It binds to the receptors for both the atrial and brain natriuretic peptides of the endothelium and vascular smooth muscle. This leads to increased production of cyclic-guanosine monophosphate, resulting in venous and arterial, and coronary vasodilation. Nesiritide

Figure 14-4 The graph illustrates our early experience with Levosimendan in children with cardiac failure. In those with acute cardiac failure (blue circles), a 24-hour infusion of levosimendan resulted in an improvement in ejection fraction from 30% to 41%. There was no significant change in ejection fraction in children with end-stage cardiac failure (red triangles). Doses of catecholamine, however, were substantially reduced in all patients.⁵⁹

also inhibits cardiac sympathetic nervous system activity, so that its vasodilator effects are not accompanied by reflex tachycardia. It also produces important renal effects, including an increase in the rate of glomerular filtration, and inhibits reabsorption of sodium, therefore leading to diuresis and natriuresis.⁶²

Clinical Effects of Nesiritide

There is mixed experience in the literature with nesiritide in adults with acute, decompensated cardiac failure. Nesiritide may be superior to dobutamine in terms of short-term survival⁶³; and the Vasodilation in the Management of Acute Congestive Heart Failure trial demonstrated superior effects on cardiac preload of nesiritide compared to nitroglycerin, although there was no difference in symptomatology.⁶⁴ A more recent pooled analysis of randomised trials of nesiritide in adults not receiving additional inotropic agents suggested that its administration might be associated with a worse outcome, which may have been related to a worsening of renal function.⁶⁵

There is growing experience of nesiritide in children, and its safety has been demonstrated in children with acute-on-chronic cardiac failure, or a low cardiac output state early after cardiac surgery. In these patients, its administration has been associated with improved urinary output, and reduction in neurohormonal markers of cardiac failure.^{66,67} As with levosimendan, further research, and in particular comparative trials, will be necessary before establishing whether or not nesiritide has a role in the primary treatment of children with cardiac disease.

Summary of Pharmacological Support in Children with Acute Circulatory Failure

The emphasis on the treatment of cardiac failure has shifted from a focus on manipulating contractility to reducing afterload, controlling systemic vascular resistance, and avoiding increases in myocardial work. Unlike adults with acute circulatory failure, children with cardiac disease present a very different range of considerations, which vary greatly between individuals. These include the relative immaturity of the pulmonary vasculature and the myocardium, the lability of the pulmonary vascular resistance, the contribution of complex circulations which are most stable in the presence of systemic vasodilation and the post-bypass circulation with elevated systemic and pulmonary resistances. Accordingly, the choice of pharmacological agents must be carefully tailored and adjusted according to the underlying diagnosis and pathophysiology for the individual patient.

Extracorporeal Support

From Pharmacology to Extracorporeal Life Support:

The Pragmatic Approach to Mechanical Support

In previous sections, I discussed how the pharmacological management of acute circulatory failure is shifting away from overworking the myocardium with pure inotropes towards enhancing cardiovascular performance using agents which reduce myocardial work. Thus, optimising the systemic balance of oxygen in cardiac intensive care now routinely employs approaches which are aimed at minimising myocardial work. Mechanical support, using extracorporeal membrane oxygenation or a ventricular assist device, provides assistance for children with acute circulatory failure, in whom intrinsic cardiovascular function cannot, with the assistance of carefully tailored pharmacological agents, adequately support the circulation. Moreover, the institution of mechanical support provides the opportunity for a period of almost complete myocardial rest.

Mechanical cardiac support should ideally be considered at a stage where the risk of escalating pharmacological agents outweighs the benefits of a period of myocardial rest, rather than a last resort treatment for patients who will otherwise surely die. This represents a philosophically unusual continuum for patients with circulatory failure, because escalation of therapy generally involves first a careful increase in vasoactive drugs, until a certain threshold is reached, at which point mechanical support is initiated and pharmacological agents are ceased.

Background: The Introduction of Mechanical Support into Intensive Care

In the early 1950s, C. Walther Lillehei changed the face of congenital cardiac surgery when he introduced the concept of extracorporeal circulation into clinical practice. The earliest application of this concept was the so-called cross-circulation, in which a healthy adult provided a living heart-lung machine to provide extracorporeal circulatory support for the child during open repair of congenitally malformed hearts.⁶⁸ Clearly cross-circulation was not likely to become a long-term option, due to the excessive hazards which it entailed. To this end, Gibbon developed the bubble oxygenator, which was first used in 1955 by Dewall and Lillehei during surgery for congenital cardiac disease.⁶⁹

Cardiopulmonary bypass, cardiac surgery and intensive care practice all progressed rapidly from this point forwards, and in the 1970s mechanical cardiopulmonary support began its transition to the intensive care unit. Refinements of oxygenators ensued, such that circuits were designed which created less haemolysis, and were viable for much longer periods, and the first reports of extracorporeal membrane oxygenation in intensive care appeared in the literature thereafter.^{70,71}

Temporary mechanical support in children with acute circulatory failure, using extracorporeal membrane oxygenation or ventricular assist devices, has been increasingly used since the late 1980s. In a historical context, extracorporeal membrane oxygenation has been the more commonly used modality for cardiac support in children. This bias can largely be attributed to the familiarity of clinicians with cardiopulmonary bypass, and historically, to the widespread use of extracorporeal membrane oxygenation for the treatment of neonatal hypoxaemic respiratory failure. Despite a recent increase in its use for cardiac support, the Extracorporeal Life Support Organisation registry report of 2007 states that, since 1989, only one-fifth of all paediatric extracorporeal membrane oxygenation has been for cardiac indications.

Determinants of Success of Extracorporeal

Life Support: Basic Principles

Extracorporeal life support is a hazardous therapy with a high associated mortality, and is only used for critically unwell children, many of whom would otherwise not survive. Given the inherent risks of this therapy, all involved clinicians are responsible for maximising the chances of its success for each individual. This requires a streamlined approach to decision-making, optimal timing of initiating support and an ongoing commitment to investigating and optimising factors which may reduce the chances of its successful discontinuation.

A Programmatic Approach

The delivery of extracorporeal life support by a dedicated team of practitioners, with appropriate training and familiarity with the technology, and collaborative decision-making contributes to the success of this complex therapy. This is achieved in part through regular use of extracorporeal support in dedicated centres, a commitment to ongoing education and a uniform approach to the design of the circuitry, and avoiding unnecessary variables which would increase the likelihood of error. In our institution for example, all circuits for extracorporeal membrane oxygenation and short-term ventricular assist use identical tubing, driver consoles, and pump heads, regardless of the underlying condition or age of the child. This approach encourages familiarity with the circuit, and therefore minimises technical errors.

The Timely Institution of Extracorporeal Life Support

The timely institution of mechanical support, rather than its use only as a rescue therapy, contributes to improved outcomes. Thus, the survival of infants and children requiring support following surgery for congenital cardiac disease is generally better when support is instituted early in the operating room rather than later in the intensive care unit.⁷² Delay in the institution of support often results in a window of opportunity for appropriate and timely intervention, and therefore the greatest chance of success, being lost. In the extreme, early intervention may prevent

Figure 14-5 The illustrated aorto-pulmonary collateral artery (arrow) caused failure to wean from cardiopulmonary bypass. It was revealed by cardiac catheterisation of the patient after stabilisation with extracorporeal membrane oxygenation.

the potentially catastrophic consequence of cardiac arrest. Although extracorporeal cardiopulmonary resuscitation is now widely available, patients cannulated during cardiac arrest may have a poorer long-term prognosis than those cannulated earlier.⁷³

Ongoing Reassessment of the Patient

An important contributor to the success of extracorporeal life support is a proactive approach to reassessment once support has been established. Although mechanical support can temporise an unstable patient, it is not an alternative for incomplete surgery, or a therapy for residual anatomic lesions. Indeed, it is widely accepted that children with residual anatomic or surgical problems do poorly unless the lesions are addressed and corrected (Fig. 14-5).⁷⁴

Mode of Mechanical Support

Extracorporeal Membrane Oxygenation

Veno-arterial extracorporeal membrane oxygenation provides circulatory support and gas exchange by draining the systemic venous blood, passing it through an oxygenator which functions as a highly efficient lung, and returning oxygenated blood to the systemic arterial circulation. This

can provide total cardiopulmonary rest for the heart with poor intrinsic function, or can provide partial support for a borderline, or recovering circulation.

Cannulation for extracorporeal membrane oxygenation can be through a sternotomy, or the peripheral route using neck or femoral vessels. The route for cannulation is dictated by the underlying pathophysiology, and the age or size of the patient. The risk of cerebral ischaemia related to carotid arterial cannulation increases with age, and the efficacy of support in terms of achievable flows, and avoidance of complications related to femoral cannulation decreases.^{75,76} Thus, cannulation for extracorporeal membrane oxygenation without sternotomy in infants and small children is generally via the carotid artery and jugular vein, whereas for older children it is typically via the femoral route (Table 14-2).

Devices for Ventricular Assistance

Temporary mechanical ventricular assistance provides support to one or both ventricles, but does not support the lungs. The basic circuitry for this type of support requires cannulation for venous drainage, and arterial return. This can be right atrial drainage and pulmonary arterial return, for patients requiring right ventricular support, or left atrial drainage and aortic return, for patients requiring left ventricular support. Cannulation for a ventricular assist device generally requires a median sternotomy, with central cannulation of the cardiac chambers or great vessels.

The popularity of temporary support with a ventricular assist device for children with ventricular failure but preserved pulmonary function has grown over the past decade,^{77,78} but still lags behind the use of extracorporeal membrane oxygenation in many institutions (Table 14-3). In contrast with extracorporeal membrane oxygenation, the circuit incorporating the ventricular assist device circuit does not include an oxygenator, which is an important source of turbulence or clot formation, and requires less systemic anticoagulation resulting in a reduced risk of bleeding.

Choice of Mechanical Support

Extracorporeal membrane oxygenation is the appropriate mode of support for patients with both cardiac and pulmonary impairment, for infants with pulmonary hypertension, or for extracorporeal cardiopulmonary resuscitation. Support with a ventricular assist device would be the preferred approach for infants or children with dysfunction of one ventricle and preserved pulmonary function, and adequate function of the contralateral ventricle. The function of the

TABLE 14-2

ROUTES OF CANNULATION FOR EXTRACORPOREAL MEMBRANE OXYGENATION

Indication	Cannulation	Comments	Reasons
Acute circulatory failure, not post-operative	Neck cannulation (carotid artery-jugular vein)	Neck cannulation for infants and younger children	Morbidity related to carotid cannulation greater in older patients.
	Femoro-femoral (femoral artery-femoral vein)	Femoro-femoral for older children (routinely consider if aged >10 yr)	Peripheral circulatory problems related to femoral cannulation greater in younger patients
	Open chest cannulation (right atrium – aorta)	Consider for overwhelming sepsis with supra-normal flow requirements	High flows achievable with larger cannulas
Post-operative circulatory failure	Open chest	If early post-operative phase	Easily accessible for rapid cannulation or conversion from cardiopulmonary bypass

TABLE 14-3

MODE OF EXTRACORPOREAL SUPPORT IN CHILDREN WITH CIRCULATORY FAILURE

Cardiac Arrest	ECMO	Default Mode of Support for Children Receiving CPR
Failure to wean from bypass or Early post-operative low cardiac output state		
Isolated ventricular dysfunction	Single VAD	
Biventricular dysfunction	BIVAD/ECMO	Institutional preference may be for ECMO, especially in smaller infants
Pulmonary hypertension	ECMO	
Functionally univentricular physiology with a systemic-to-pulmonary artery shunt	ECMO/VAD	Identical cannulation but no oxygenator for VAD Shunt restriction may be appropriate
Acute myocarditis	ECMO	With left atrial decompression
Decompensation of chronic cardiac failure	Single VAD	Unless cardiac arrest or poor lung function

BIVAD, biventricular assist device; CPR, cardiopulmonary resuscitation; ECMO, extracorporeal membrane oxygenation; VAD, ventricular assist device.

opposite ventricle does not need to be entirely normal, as inotropic therapy at low doses and/or afterload reduction, may adequately support this. Careful assessment of both ventricles, and pulmonary function is, therefore, essential prior to instituting support. The timing of the introduction of a device providing ventricular assistance is key to its success, and it is most likely to prove efficacious if commenced in the operating room, or very early after surgery in the intensive care unit. Significant delays may otherwise result in a missed window of opportunity, necessitating the more urgent institution of extracorporeal membrane oxygenation.

In patients with biventricular dysfunction and adequate pulmonary function, the decision to use extracorporeal membrane oxygenation or biventricular assist devices for temporary circulatory support is more open to debate, particularly in small children. The ultimate choice is usually dictated by institutional preference. In transplant centres where biventricular assist devices are frequently used as a bridge to transplantation in children, then this may also be the preferred modality for temporary support.⁷⁹ Others would consider that the complexity of four cannulas, significant cardiectomy and the requirement to synchronise ventricular outputs for biventricular assist devices would outweigh the potential disadvantage of an oxygenator in the circuit for extracorporeal membrane oxygenation.

Indications for Extracorporeal Life Support

The most common indication for cardiac support in infants and children is post-operative circulatory failure. Extracorporeal support has a well-established role in the acute, short-term support for infants and children with a critical low cardiac output state early after surgery for congenital heart disease,⁷⁷ the treatment of children with fulminant myocarditis,^{80,81} post-operative pulmonary hypertension⁸² and early graft failure after cardiac transplantation.⁸³ More recently, rapid-deployment extracorporeal membrane oxygenation has become established as a resuscitative tool in infants and children during cardiac arrest.⁸⁴

At the Royal Children's Hospital, Melbourne, between 1989 and 2006, 229 infants and children received mechanical support early after cardiac surgery, which represents

an overall rate of 2.9% of cardiac surgical patients. The predominant indications for support were an inability to wean from bypass or failure to respond to maximal medical therapy in the intensive care unit, which together account for more than two-thirds of patients requiring cardiac support at our centre.

Criteria for Support

The spectrum of patients for whom mechanical support is offered has broadened over the past decade, and strict criteria for support no longer exist. In principle, support should only be considered if the patient is expected to recover to a reasonable level of function with or without additional intervention.

Contra-indications to Extracorporeal Life Support

The presence of severe pre-existing cerebral injury, or a new parenchymal intracerebral haemorrhage, would be considered to be relative contra-indications to mechanical support in most centres undertaking extracorporeal life support. This is because mechanical support carries a significant risk of causing new haemorrhage, or worsening of existing bleeds, and additional ischaemic or embolic cerebral injury. Although there are well-recognised groups of patients known to be at high risk (see below), there are no diagnostic subgroups for whom mechanical support would be absolutely contra-indicated. Patients with severe residual anatomic lesions that cannot be addressed, nonetheless, would be considered poor candidates for support in most centres, for example, infants with totally anomalous pulmonary venous connection and diffuse pulmonary venous stenosis, who cannot be weaned from bypass.

Groups of Patients Known to Be at High Risk

Historically, complex palliated circulations such as the Fontan circulation were associated with poor outcomes, and therefore were considered by many to be unsuitable for extracorporeal support.^{85,86} Outcomes for these patients have, however, improved somewhat since the early 1990s. Thus, while accepting that these patients still carry the highest mortality, most centres now occasionally support patients after conversion to the Fontan circulation, along with children having bidirectional cavopulmonary shunts.⁸⁷

Young infants with a surgically palliated functionally univentricular circulation and a systemic-to-pulmonary

artery shunt continue to present a challenge. This circulatory physiology was previously considered to be a relative contra-indication to mechanical support.⁸⁶ Over recent years, the overall outcomes of support for these patients has improved. This is for a combination of reasons, including earlier institution of support, the advent of programmatic rapid-deployment, the increased use of a ventricular assist device, and refined approaches to management of the shunt (see below).^{88,89}

Special Considerations for Children Receiving Extracorporeal Life Support

The Systemic-to-Pulmonary Arterial Shunt

Infants with a functionally univentricular circulation, with shunt-dependent pulmonary flow, were historically considered poor candidates for mechanical support. In these infants, complete occlusion of the shunt was traditionally performed during cannulation for extracorporeal membrane oxygenation, in order to prevent the sequels of uncontrolled pulmonary flow, and compromised systemic perfusion. Although this approach was theoretically reasonable, it was proposed that an important contributory factor towards the dismal outcome for this group was their totally absent pulmonary perfusion.⁹⁰ This theory is now supported by the observations that outcomes of infants with this physiology have improved with less aggressive management of the shunt,⁹¹ such that it is now usual practice to leave the shunt either completely patent or minimally restricted during extracorporeal membrane oxygenation.⁸⁸

As for all patients, mechanical support with a ventricular assist device would be the modality of choice for infants with a functionally univentricular circulation and a low cardiac output who have preserved pulmonary function. However, with this mode of support, one ventricle must supply sufficient blood for both the systemic and pulmonary circulations, and hence the shunt must be completely patent. Thus, the total flows provided by a ventricular assist device must take into account this fact, and higher than standard flows should initially be used.

Decompression of the Left Heart on Extracorporeal Membrane Oxygenation

The majority of children with isolated, severe left ventricular dysfunction are placed on a left ventricular assist device. In these patients, the routine left atrial cannulation usually provides excellent decompression of the left heart, and additional intervention is not required. On some occasions, for example in the setting of fulminant myocarditis, where rapid cannulation and temporary pulmonary support may be required, patients may initially be placed on veno-arterial extracorporeal membrane oxygenation. In these patients, severe dilation of the left heart may accompany the initiation of extracorporeal membrane oxygenation. The reason for this is that continued right ventricular ejection results in pulmonary venous return to the left atrium, which in turn exacerbates left atrial and ventricular dilation. This vicious cycle of increased wall stress, left atrial hypertension, and pulmonary venous congestion defeats one of the purposes of support, which is to rest the heart and the lungs. Such dilation of the left heart may be in part be off-set by the use of higher flows, diuretics, afterload reduction, or gentle inotropic support to encourage ejection. Unfortunately these measures often prove inadequate, especially in the setting of left ventricular standstill when the aortic valve remains closed. Decompression of

the left heart should therefore be routinely considered at the time of cannulation. In children with an open sternum, such decompression can be achieved by directly placing a cannula in the left atrium, which drains left atrial blood into the venous component of the extracorporeal circuit. Decompression of the left heart can also be performed via the transcatheter route, using a blade septectomy followed by either balloon septostomy or transcatheter cannulation of the left atrium.⁹²⁻⁹⁴

Anomalous Left Coronary Artery from the Pulmonary Trunk

An excellent example of a homogeneous group of patients with favourable outcomes for left ventricular assistance are infants following repair of anomalous left coronary artery from the pulmonary trunk. These patients typically have critically depressed pre-operative left ventricular function, with elevated left atrial pressures and left ventricular end-diastolic pressure, and commonly suffer from low cardiac output early after surgery. Many centres, including our own, have tended to manage borderline patients with a short period, usually 2 to 3 days, of semi-elective mechanical support with a device providing left ventricular assistance immediately after bypass, in preference to substantial doses of vasoactive drugs.

The Role of Echocardiography for Patients on Extracorporeal Life Support

Echocardiography plays an important role throughout the clinical course of infants and children receiving extracorporeal support (Table 14-4). Echocardiographic assessment of myocardial function may assist the early decision-making regarding whether or not to initiate support for a borderline patient. The careful assessment of the degree of dysfunction of one or both ventricles is critical in deciding whether single ventricular assistance will suffice, or whether biventricular assistance or extracorporeal membrane oxygenation would be better for the individual patient (Fig. 14-6). Echocardiography is also an essential tool in assessing the adequacy of surgical repair, and in identifying or excluding additional surgical or anatomic defects that may be contributing to lack of response to conventional therapy.

Once a child has been placed on support, echocardiography plays a continuing, and equally important role in the subsequent assessment of the adequacy of support, the ongoing assessment for residual anatomic defects, the response to therapy, the assessment of ventricular ejection and the presence of complications. Echocardiography is also a necessary tool to assess the clinical recovery, and response of the heart to weaning from mechanical support (see Table 14-4).

Weaning from Mechanical Support

When temporary mechanical support is initiated in children, the likely duration of support should be known, and this depends upon the indication for support. For children with acute myocarditis, or end-stage myocardial disease, there may be the expectation on initiation of support, that this will be required for up to several weeks or even as a bridge to transplantation.⁸⁰ In post-surgical patients, where support is provided for a low cardiac output state, or after cardiovascular collapse, native myocardial recovery should be achieved within 3 to 5 days of commencing mechanical support. Successful weaning and long-term survival without transplantation become much less likely when support is required beyond 7 days in post-cardiotomy patients.⁷³

TABLE 14-4

THE ROLE OF ECHOCARDIOGRAPHY IN PATIENTS RECEIVING EXTRACORPOREAL LIFE SUPPORT

	Extracorporeal Membrane Oxygenation	Left Ventricular Assist Device
Pre-cannulation Echocardiography		
Ventricular function	Careful assessment essential	Right ventricular function and pressures Additional afterload reduction or inotropes may be required to assist non-supported ventricle
Atrial septal defect	Beneficial for left heart decompression	Will create right-to-left shunt
Residual defects	Early identification will lead to early attention	Early identification will lead to early attention
Aortic regurgitation	Severe regurgitation precludes good support	Severe regurgitation precludes good support
Post-cannulation Echocardiography		
Cannula position	Careful assessment essential	Careful assessment essential
Ventricular function		Right ventricular function and pressures Is single ventricular support adequate? Additional afterload reduction or inotropy may be required to assist non-supported ventricle
Adequacy of decompression	Left atrial decompression may be required	Should be excellent if cannula well-positioned
Presence of residual defects	Early identification will lead to early attention	Early identification will lead to early attention
Troubleshooting (clots, effusion)	Careful assessment essential	Careful assessment essential
Intervention	To guide atrial decompression	
Echocardiography During Weaning		
Ventricular function	Ventricular recovery during weaning and introduction of additional therapies	Ventricular recovery during weaning and introduction of additional therapies
Response to drugs, pacing	To guide timing of decannulation	To guide timing of decannulation

Successful weaning from mechanical support includes a careful assessment of the heart and circulation, with specific attention to excluding residual anatomic or surgical abnormalities. It is essential routinely to search for a remediable cause in all children who are placed on post-operative support, rather than simply assume that this is due to a long or high-risk operation. This requires detailed transthoracic or transoesophageal evaluation. If there remains suspicion that there may be an anatomic cause which is not explained by echocardiography alone, then cardiac catheterisation or further radiological evaluation, for example using computerised tomographic angiography, should be undertaken

early to utilise the window of opportunity for transcatheter or surgical intervention.⁹⁵ Examples of residual lesions which may preclude successful weaning are significant aortopulmonary collateral vessels, distal pulmonary arterial obstruction, arrhythmic ablation and persisting additional intracardiac shunts.

The technical aspects of weaning from extracorporeal support vary according to the mode of support, the underlying indication, and the urgency of the need to separate from support. There are, however, some broad principles that apply for all patients, which are aimed at optimising their condition prior to separation from support. Weaning

Figure 14-6 The images demonstrate the value of intra-operative transoesophageal echocardiography during institution of ventricular assistance in a child with ventricular failure. Initially, the child was placed only on left-sided support. The echo to the left shows complete obliteration of the left ventricular cavity, with the right ventricle remaining dilated and poorly functioning. Right-sided cannulation was therefore performed, and the child was placed on biventricular support (*right*).

from mechanical support is a process where the flows on the extracorporeal circuit are reduced over a period of at least several hours. During this time, the performances of the myocardium and for many patients, their lungs, are being tested. In order to maximise the chances of success, it is essential to ensure that pulmonary function is optimal prior to weaning, and that appropriate inotropic and after-load reducing agents, in some cases including inhaled nitric oxide, have been commenced and appropriately titrated. In addition, it is sensible to introduce measures aimed at reducing the consumption of oxygen, including high levels of sedation and analgesia, and muscle relaxants.

Risks of Extracorporeal Life Support

Mechanical support is a hazardous therapy, and mortality is often related to complications rather than to the underlying disease. Extracorporeal support carries a significant risk of haemorrhage, which is directly related to the level of systemic anticoagulation. In addition, the extracorporeal circuit can cause haemolysis, or can precipitate formation of thrombus, with the potential to embolise to the circulation, or to cause occlusion of the circuit. The risk of these complications is related to the complexity of the circuit and is also increased by the presence of an oxygenator, which further reinforces the use of a ventricular assist device wherever possible. Patients on mechanical support are at significant risk of sepsis. This is related to deconditioning of the patient, exposure to artificial surfaces, the presence of cannulas, multiple surgical sites, and in some the need for the chest to be kept open. All of the risks increase with the duration of mechanical support, which reinforces the need for constant reassessment of circulation, and timely weaning from support.

Survival

The worldwide survival to hospital discharge for children receiving extracorporeal life support for cardiac disease is now between 40% and 50%.^{77,88,96} This figure has remained relatively stable over the past decade, though increasing proportions of patients at higher risk are now receiving support. When diagnostic subgroups are considered, survival is lowest for infants with a cavopulmonary connection, and those with functionally univentricular circulation supported with extracorporeal membrane oxygenation for a low cardiac output. Conversely, a survival of greater than 80% is reported for infants after the first stage of surgical reconstruction for hypoplastic left heart syndrome, when extracorporeal membrane oxygenation was initiated for acute shunt occlusion.^{88,97} Other factors which may be associated with reduced survival include a longer duration of support, the presence of additional organ dysfunction and the development of sepsis, haemorrhage or abnormal neurology.^{77,89,96,98–100} In our own institution, survival has improved over the past two decades, despite our recent use in higher-risk patients, and as a resuscitative tool (Fig. 14-7). The likely reasons for this improvement include the establishment of a dedicated team, careful selection of patients, an algorithmic approach to the choice of support for specific diagnostic groups, the earlier deployment of support in patients at high risk of acute deterioration, refinements in components of the circuit and minimising variables within the circuit. The outcome of children receiving mechanical support should not be limited to discussing survival. Extracorporeal life support carries with it substantial additional risk of long-term neurodisability,

Figure 14-7 The graph shows the improved outcomes from extracorporeal membrane oxygenation in children with cardiac disease in Melbourne, illustrating survival to discharge from hospital for the first 110 infants and children who received such cardiac support at the Royal Children's Hospital, Melbourne.

and this is more common in children receiving extracorporeal membrane oxygenation than temporary support with a ventricular assist device. Long-term neuromotor and cognitive outcomes may be adversely affected in at least half of the survivors, and this reinforces the need for their continued neurodevelopmental surveillance.^{101,102}

Summary of Extracorporeal Life Support for Acute Circulatory Failure

Over the past 2 decades, there have been remarkable advances in the field of extracorporeal support in children with circulatory failure, which have been associated with improved outcomes in increasingly complex groups of patients. These advances include the programmatic approach to support, refinements in circuitry, proactive decision-making and a better understanding of the circulatory physiology of patients during acute mechanical support.

When considering mechanical support for children with cardiac disease, and when talking to their families, it is essential to be fully informed that this therapy is not a panacea, but provides temporary support with the hope of enabling myocardial recovery after the insult of surgery, infection, or other causes of cardiovascular decompensation. The initiation of support should herald the start of a timer for clinicians who have a limited window of opportunity to optimise cardiovascular function, while considering additional investigation and therapeutic intervention, in order to maximise the chance of weaning from support.

When considering survival, successful decannulation should not be used as an end-point, as this step is relatively early in the protracted clinical course of most of these patients. Discharge home is a more appropriate marker of survival, but this statistic still masks a significant proportion of patients who may not be neurologically intact. The success of extracorporeal life support should ideally be defined in terms of neurologically intact survival, in a patient with adequate cardiac function.

TABLE 14-5

SUMMARY OF KEY THERAPEUTIC INTERVENTIONS FOR INFANTS AND CHILDREN WITH ACUTE CIRCULATORY FAILURE

Category	Example	Ventilation	Pharmacology	Extracorporeal Life Support
Systolic +/- diastolic dysfunction Increased afterload	Post-operative cardiac	Positive pressure ventilation is beneficial → Reduced LV afterload and RV preload)	Systemic vasodilators, careful inotrope therapy → Reduction in LV afterload, increased contractility	Early institution, usually open chest Single VAD preferable if lung function adequate and not emergency ECMO if cardiac arrest
Normal total cardiac output Maldistribution of pulmonary/systemic flow	Functionally univentricular heart	Positive pressure ventilation to stabilise the pulmonary vascular resistance (pre- and post-operative)	Systemic vasodilation Gentle inotropic support if impaired systolic function	Post-operative principles: Early institution if persisting acidosis and systemic hypoperfusion VAD if not-emergency ECMO if cardiac arrest
Normal systolic function Diastolic dysfunction	Post-operative Fontan Post-operative tetralogy of Fallot	Positive pressure ventilation is generally detrimental Aim for early extubation	Low dose noradrenaline may be beneficial Inotropes and vasodilators not generally useful	Uncommon indication Rarely necessary if appropriate use of other modalities and if residual lesions are excluded
Residual anatomic lesions	Post-operative cardiac	Routine positive pressure ventilation according to lesion	Careful use of all drugs, especially if fixed obstruction	Can be used to temporise the situation, and to enable investigations under more controlled conditions. Poor outcome if lesions are uncorrected.
Normal function Reduced afterload	Septic shock	At risk of systemic ventricular failure, and pulmonary oedema Positive pressure ventilation is beneficial.	First line: dobutamine + noradrenaline—commonly used in combination.	ECMO if systemic hypoperfusion and multi-organ dysfunction Consider sternotomy for high flow requirements.

ECMO, extracorporeal membrane oxygenation; LV, left ventricular; RV, right ventricular; VAD, ventricular assist device.

Summary of Treatment of Acute Circulatory Failure in Children

Acute circulatory failure is a multi-factorial phenomenon in children with heart disease, and its pathophysiology and haemodynamic manifestations are very variable. The successful treatment of children with circulatory failure requires a good understanding of the underlying disease and associated physiology, and a proactive approach to treatment using carefully tailored therapeutic interventions. The importance of considering the underlying physiology prior to managing circulatory failure in children cannot be over-emphasised. Indeed, the strategies for treating two patients with similar clinical manifestations of a low cardiac output may be very different, the treatment for one child being detrimental to the other.

The use of ventilation, cardiovascular drugs and mechanical support is aimed at providing short-term support for children at risk of developing circulatory failure, or for those who have developed this phenomenon. These strategies are often used in combination, and are aimed at assisting the heart and circulation to recover from an identifiable insult, but should not be expected to provide an alternative to reintervention for a significant anatomic problem (Table 14-5).

ACKNOWLEDGEMENTS

I would like to acknowledge the contributions of my friends and colleagues, Associate Professor Warwick Butt, lead in extracorporeal life support, and Mr Derek Best, coordinator for extracorporeal life support, at the Royal Children's Hospital, Melbourne, Australia.

A systematic review of the role of non-invasive positive pressure ventilation in the treatment of acute heart failure in adults. This review considered the available evidence, from randomised controlled trials and systematic reviews, and concluded that non-invasive ventilation reduced the need for intubation and mortality.

- Shekerdemian LS, Shore DF, Lincoln C, et al: Negative-pressure ventilation improves cardiac output after right heart surgery. *Circulation* 1996;94(9, suppl):II49–II55.

This was the first of several clinical investigations by these authors, of negative pressure ventilation in infants and children with congenital heart disease. A brief period of negative pressure ventilation in children early after surgery, resulted in increases in cardiac output of 46% in ventilated children early after Fontan operations or tetralogy of Fallot repair. This study, and others by the same group, used a cuirass negative pressure ventilator to mimic spontaneous respiration, and conclusively demonstrated the importance of the early establishment of spontaneous respiration in these patients.

- Tworetzky W, McElhinney DB, Reddy VM, et al: Improved surgical outcome after fetal diagnosis of hypoplastic left heart syndrome. *Circulation* 2001;103:1269–1273.

This retrospective cohort analysis of 88 infants with hypoplastic left heart syndrome reinforces the important role of pre-operative clinical status in determining the early outcome of these patients. Infants with a prenatal diagnosis were in better clinical condition early after birth and before surgery, and this impacted upon the subsequent clinical course after surgery. Specifically, acidosis, ventricular dysfunction and the need for inotropes, in the pre-operative period, were significant predictors of adverse outcome. These negative factors were associated with a postnatal diagnosis.

- Tweddell JS, Hoffman GM: Postoperative management in patients with complex congenital heart disease. *Semin Thorac Cardiovasc Surg Pediatr Card Surg Annu* 2002;5:187–205.

Infants with complex heart disease, in particular hypoplastic left heart syndrome and its variants, present a challenge in intensive care. This review focuses upon the optimisation of the systemic delivery of oxygen in these infants early after surgery. The authors report an approach which uses vasodilator therapy to improve systemic perfusion in the context of goal-directed therapy.

- Hoffman TM, Wernovsky G, Atz AM, et al: Efficacy and safety of milrinone in preventing low cardiac output syndrome in infants and children after corrective surgery for congenital heart disease. *Circulation* 2003;107:996–1002.

The low output state affects around one in four children early after cardiac surgery. An important focus of modern cardiac intensive care is the prevention of this phenomenon. Milrinone is a vasodilator with possible inotropic effects. This prospective, randomised, controlled study in 227 children undergoing complete biventricular repairs of congenital heart disease, cardiac repairs, demonstrated that prophylactic high-dose milrinone, given early after cardiopulmonary bypass, reduced the risk of a low output state from 26% to 12%.

- Stocker CF, Shekerdeman LS, Nørgaard MA, et al: Mechanisms of a reduced cardiac output and the effects of milrinone and levosimendan in a model of infant cardiopulmonary bypass. *Crit Care Med* 2007;35:252–259.

In this laboratory model of infant cardiopulmonary bypass, increased afterload and impaired ventriculo-vascular coupling, without sufficient compensation, were found to be the most significant precipitants of the reduced cardiac output early after heart surgery. In this model, milrinone and levosimendan both prevented this deterioration and benefitted myocardial oxygen balance and pulmonary vascular resistance. In addition, levosimendan had additional inotropic properties which would suggest that it may be a superior agent in the peri-operative management of high-risk infants undergoing cardiopulmonary bypass.

- Chaturvedi RR, Macrae D, Brown KL, et al: Cardiac ECMO for biventricular hearts after paediatric open heart surgery. *Heart* 2004;90:545–551.

The timing of institution of extracorporeal support is likely to influence outcome of this high-risk and complex therapy. This retrospective review of 81 children undergoing extracorporeal membrane oxygenation after cardiac surgery in a single centre reported a survival to hospital discharge of 49% (in keeping with worldwide experience). Survival rates were higher for patients in whom support had been initiated in the operating room (64% survival) and much lower if support was commenced in the intensive care unit (29% survival). The authors suggested that earlier institution of support was likely to prevent ongoing systemic hypoperfusion, and on occasions, the catastrophic complication of cardiac arrest.

- Duncan BW: Pediatric mechanical circulatory support. *ASAIO J* 2005;51:ix–xiv.

This comprehensive review considers the extensive use of extracorporeal membrane oxygenation, and the growing (though less common) use of ventricular assist devices in children with heart disease.

- Booth KL, Roth SJ, Perry SB, et al: Cardiac catheterization of patients supported by extracorporeal membrane oxygenation. *J Am Coll Cardiol* 2002;40:1681–1686.

The importance of detailed reassessment of patients requiring mechanical support cannot be overstated. This review of cardiac catheterisation of children receiving extracorporeal membrane oxygenation in a single institution demonstrates the importance of reinvestigation in this population. Sixty catheterisations resulted in an additional intervention (either transcatheter or surgical) on 50 occasions, with only minimal additional morbidity, and no directly-associated mortality.

Chronic Cardiac Failure: Physiology and Treatment

ROBERT E. SHADDY and DANIEL J. PENNY

Chronic cardiac failure has long been recognised as a cause of considerable mortality and morbidity in the adult. The early recognition of cardiac failure in the 17th and 18th centuries was that of oedema, anasarca and dyspnoea, which was appropriately attributed to blood backing up behind an impaired pump, the heart.¹ Early descriptions of cardiac failure in children, which were rare, were usually associated with rheumatic fever. It wasn't until 1936 that Abbott mentioned cardiac insufficiency as a cause of death in children,² although we now recognise that chronic cardiac failure and cardiomyopathy are indeed important causes of morbidity and mortality in children. For children with cardiomyopathy entering a national population-based registry in Australia between 1987 and 1996, the freedom from either transplant or death at 5 years after diagnosis was only 83% for patients with the hypertrophic³ and 63% for those with the dilated⁴ form of the disease.

The concepts which underlie our understanding of chronic cardiac failure in both children and adults have changed considerably in recent years. In this chapter we aim to summarise some of the current concepts related to key pathophysiological processes in chronic cardiac failure and examine outcomes from its treatment. This chapter will complement comprehensive reviews related to the different types of cardiomyopathy and to the role of imaging in this condition which are presented elsewhere in this textbook.

BASIC CONCEPTS IN CHRONIC CARDIAC FAILURE

While for centuries cardiac failure was considered to be the result of a severe and irreversible injury to the heart, which led to an irremediable abnormality of the systolic function of the ventricle, it is now recognised that the syndrome of cardiac failure reflects a more complex, dynamic and progressive process which can no longer be defined in simple haemodynamic terms and which impacts, not only on the heart itself, but on a myriad of extracardiac physiological processes.

The current framework within which cardiac failure is now considered is one in which a primary insult to the heart, whether due to ischaemia, infection, altered cardiac load or tachycardia, results in a cascade of secondary responses within the heart itself and within related organs.^{5,6} It appears that irrespective of the precise nature of the primary insult, for the most part, the secondary responses and the clinical evolution share common features, so that the progression of cardiac failure represents

an ordered, predictable, coordinated cascade of events, which although initially reversible, in the absence of treatment may result in terminal cardiac failure and ultimately death.⁶

It appears that these secondary responses to cardiac injury may, at least in the initial phase, be adaptive and designed to preserve the flow of blood to the vital organs.⁶ Thus in response to a regional injury of the myocardium, the global cardiac function is maintained by invoking a number of compensatory mechanisms. The regional function of the uninjured myocardium increases and the ventricle hypertrophies as growth factors within the myocyte accelerate the synthesis of protein and growth of the myocyte. As will be described later, within the kidneys, a reduction in renal perfusion pressure is detected by receptors in the renal arterioles which leads to the release of renin. The subsequent formation of angiotensin II results in constriction of the efferent arterioles so that the glomerular filtration pressure is maintained. Angiotensin also stimulates the synthesis of aldosterone which results in the retention of salt and water by the kidney. As a result, reductions in systemic and renal perfusion pressure are attenuated by vasoconstriction and retention of salt and water. Activation of the neuroendocrine system, manifest by the systemic release of neurohormones such as noradrenaline and adrenaline maintain cardiac output through their chronotropic and inotropic properties.

With time these mechanisms become maladaptive as the patient progresses into a phase of decompensated cardiac failure.⁵ The increase in the mass of the left ventricle, combined with its dilation augment the mural stress within the myocardium and its consumption of oxygen, potentially worsening the myocardial injury. Chronic activation of the renin-angiotensin system results in oedema, elevations of pulmonary arterial pressure and increased afterload. Sympathetic activation increases the risk of arrhythmia and sudden death. While these changes may be reversed by successful treatment, it has been suggested that such treatment must be initiated before the patient reaches the so-called terminal threshold that is a point after which recovery of left ventricular function is not possible⁷ (Fig. 15-1).

THE FUNCTION OF THE NORMAL AND THE FAILING HEART

The ability to accurately describe the function of the heart, its metabolic demands and its interactions with the vasculature, is of paramount importance in analysing the mechanisms of circulatory failure and the effects of interventions in patients with myocardial disease. In clinical practice our

Figure 15-1 The responses to myocardial injury. Injury results in adaptive responses within the heart and within related systems. As the condition progresses, these adaptive responses become counterproductive (maladaptive) leading to progression of the disease and increasing symptoms. Treatment may reverse these maladaptive changes until a terminal threshold is reached, after which recovery of left ventricular function is not possible and irreversible cardiac failure ensues. (Modified from Delgado RM, 3rd, Willerson JT: Pathophysiology of heart failure: A look at the future. *Tex Heart Inst J* 1999;26:28–33.)

assessment of cardiac function is usually limited to the indirect estimation of ventricular systolic and end-diastolic pressure, ejection fraction, and in some echocardiography laboratories, the assessment of mural stress. However, a complete evaluation of cardiac function would extend further, ideally to include an indicator of ventricular systolic and diastolic performance that is relatively independent of load, an assessment of the myocardial consumption of

oxygen and an examination of the relationship between ventricular performance and cardiac load.

Since Suga presented his analysis of the instantaneous pressure-volume relationship,⁸ and subsequently developed the concept of time-varying elastance,⁹ there has been heightened interest in the use of the pressure-volume relationship in assessing ventricular performance, especially in recent years with the introduction of the conductance catheter technique¹⁰ which allows high-fidelity on-line measurements of ventricular pressure and volume at fast acquisition speeds.

The classic work of Wiggers¹¹ which described changes in left ventricular pressure and volume during the cardiac cycle has provided the foundations for our current understanding of ventricular function. In Wiggers' schema the cardiac cycle begins with the onset of depolarisation on the electrocardiogram, which is soon followed by an increase in pressure within the ventricle. When left ventricular pressure exceeds left atrial pressure the mitral valve closes. The aortic valve remains closed while aortic pressure still exceeds left ventricular pressure, and ventricular volume therefore remains constant: so-called isovolumic contraction. When left ventricular pressure exceeds aortic diastolic pressure, the aortic valve opens and the ventricle begins to eject. Consequently the volume of the left ventricle falls (Fig. 15-2).

Diastole is traditionally assumed to begin with closure of the aortic valve; however the decay in ventricular pressure (relaxation) begins before this event. After aortic valve closure, ventricular pressure continues to decay rapidly resulting from the energy-requiring mechanism, together with the passive release of myocardial elastic forces generated during contraction. As the ventricular pressure continues to decay, the mitral valve initially remains closed and the period of relaxation during which ventricular volume remains constant, is termed isovolumic relaxation.

Figure 15-2 The temporal changes in the volume of the left ventricle (LV), as well as the pressures within the left atrium (LA), the left ventricle and aorta during the cardiac cycle (left). The onset of the isovolumic contraction time begins at I, when the pressure in the ventricle exceeds that within the atrium. This period ends at II, with the onset of ejection as the pressure within the ventricle exceeds that in the aorta. The period of isovolumic relaxation begins at III when the pressure in the left ventricle falls below that in the aorta. Filling of the ventricle begins at IV, when ventricular pressure falls below that in the atrium. The right hand panel represents the instantaneous relationship between the pressure and volume in the ventricle, with the time points represented as I to IV corresponding to the same events as those for the left hand panel.

When ventricular pressure falls below atrial pressure, the mitral valve opens and ventricular filling begins. During the early period of ventricular filling its pressure falls. This anomalous relationship between pressure and volume is thought to result from restoring forces, which attempt to restore the shape of the ventricle to that at end-diastole. After this time, both pressure and volume increase in the ventricle, which exhibits elastic behavior. Later in diastole the rate of ventricular filling is further augmented by atrial contraction.

Examination of Cardiac Function with the Pressure-Volume Loop

While until now, we have considered the temporal changes in left ventricular pressure and volume, the essence of the pressure-volume analysis is to consider the time-varying relationship between ventricular pressure and volume, represented by the pressure-volume loop. The pressure-volume loop has four characteristic phases. Beginning at its bottom right corner, an initial upstroke (I to II; see Fig. 15-1) represents the rapid increase in ventricular pressure, with little volume change: isovolumic contraction. There is then a rapid fall in ventricular volume, as ventricular ejection proceeds to the end-systolic point (II to III). Ventricular pressure then rapidly falls, with little volume change, as the ventricle enters the isovolumic relaxation phase (III to IV). Finally, ventricular volume increases to its end-diastolic level, reflecting ventricular filling (IV to I).

Suga noted that at constant inotropic state, alterations in ventricular load resulted in a population of pressure-volume loops in which, at any time in the cardiac cycle, the pressure-volume points follow a straight line. It was proposed therefore that cardiac contraction could be modelled as a time-varying elastance, with maximal elastance occurring at end-systole (end-systolic elastance),⁹ represented by the upper left hand corner of the pressure-volume loop (Fig. 15-3).

While the end-systolic pressure-volume relationship has been considered the definitive measure of ventricular

contractility, the importance of other indices should not be underestimated. It is important to emphasise that there is no single gold-standard measure, which will encompass the complex physiologic processes which determine myocardial contractility, rather, there are a number of measures, each of which provides individual pieces of a complex jigsaw.

It must be appreciated that the pressure-volume relationship provides a wealth of information about cardiovascular physiology beyond end-systolic elastance on which we will now concentrate.

The intricate coupling between the ventricle and the vasculature is an extremely important clinical determinant of cardiovascular function. While many treatments for cardiac failure are aimed at augmenting ventricular systolic performance, it is clear that without the ability of the vasculature to convert within itself the increased pressure work of the ventricle into flow work, these therapeutic strategies would be of little benefit. One measure of the efficiency of ventriculo-vascular coupling, based on an examination of the pressure-volume relationship, examines the coupling between end-systolic elastance and arterial elastance¹² to illustrate how the arterial response determines the physiological effect of an increase in contractility during inotropic stimulation.

The pressure-volume relationship can also provide important information regarding the energetic state of the ventricle. As in many critically ill patients with myocardial disease, the relationship between myocardial oxygen demand and supply is already precarious, it is imperative that any potentially desirable augmentation of ventricular performance should not be off-set by adverse effects on myocardial metabolism and energetics. Suga demonstrated that the total energy consumption of the ventricle can be quantified by the specific area in the pressure-volume diagram that is bounded by the end-systolic and end-diastolic pressure-volume relations and the systolic pressure-volume trajectory.¹³ The scope of the pressure-volume diagram therefore extends beyond cardiac mechanics to include cardiac energetics and mechanoenergetic coupling under varying contractile conditions.

Figure 15-3 Changes in left ventricular pressure, volume, and rate of change of pressure (dP/dt) recorded with a conductance catheter during caval occlusion (*left*). A series of pressure-volume loops is generated (*right*) with a linear relationship between pressure and volume at end-systole.

Figure 15-4 Dyssynchrony of left ventricular function, demonstrated with tissue Doppler imaging. The time to the peak of inward movement of the lateral part of the annulus occurs 150 msec after the peak inward movement of the central fibrous body.

The use of the pressure-volume relationship to assess the diastolic properties of the ventricle is based on the assumption that throughout the period during diastole when both volume and pressure are increasing, the ventricle exhibits elastic behaviour. As a result, at any point during this time, the slope of the relationship between pressure and volume represents ventricular compliance. As the normal pressure-volume relation at this time is curvilinear, chamber compliance becomes lower as filling proceeds, indicating that the cavity has become stiffer. The pressure-volume curve during this part of diastole is usually assumed to be exponential and to show behaviour characteristic of Lagrangian stress, so that, if pressure is plotted logarithmically and volume linearly, then a linear relationship will be obtained; it is then possible to calculate its slope and intercept.

There is little data which addresses the changes which occur in the ventricular pressure-volume relationship in children with myocardial failure. However, studies in adults have shown that the assessment of the pressure-volume relationship can be used to assess the effects of progressive myocardial failure on integrated cardiovascular performance.

Studies which investigated the matching of ventricular properties to arterial load, are particularly important in this respect. In normal subjects with an ejection fraction of 60% or more, ventricular elastance is nearly double arterial elastance. This condition affords an optimal coupling between ventricular work and oxygen consumption. In patients with moderate cardiac failure, with ejection fractions of 40% to 59%, ventricular elastance is almost equal to arterial elastance, a condition affording maximal stroke work from a given end-diastolic volume. However, in patients with severe cardiac failure, with ejection fraction of less than 40%, ventricular elastance is less than

half of arterial elastance, which provides a suboptimal relationship between ventricular work and either oxygen consumption or stroke volume. These studies suggest that ventriculo-arterial coupling is normally set towards maximising work efficiency in terms of the relationship between left ventricular work and oxygen consumption. As cardiac function becomes impaired, in patients with moderate cardiac dysfunction, ventricular and arterial properties are initially matched, in order to maximise stroke work at the expense of work efficiency. However, as cardiac dysfunction becomes severe, the ventricle and vasculature become uncoupled, so that neither the stroke work nor work efficiency is near maximum for patients with severe cardiac dysfunction.^{14,15}

While until now we have considered the function of the left ventricle as a whole, dyssynchrony of left ventricular function is frequently observed in patients with cardiac failure, in whom it results in inefficiencies in the contraction of left ventricle, a decreased cardiac output and increased risk of sudden cardiac death (Fig. 15-4). Recently, new therapies aimed at restoring mechanical synchrony in such patients have been shown to result in reductions in symptoms and improvements in outcomes.¹⁶

THE CELLULAR PHYSIOLOGY OF THE CARDIAC MYOCYTE

Before discussing the cellular mechanisms associated with the development of myocardial failure, it is necessary to examine the structure and function of the normal cardiomyocyte. In this section we will examine some of the principles related to this topic, although will not provide a comprehensive review of the multitude of intracellular and intercellular messengers, as these have been considered in

some excellent specialist reviews.^{17–19} Rather we aim to outline some of the principles.

Cardiac myofibres are composed of groups of muscle cells (cardiac myocytes) connected in series and surrounded by connective tissue. Each cardiomyocyte is bounded by a thin bilayer of lipid (the sarcolemma) and contains bundles of myofibrils, arranged along its long axis. These myofibrils, in turn, are formed of repeating sarcomeres, the basic contractile units of the cell, composed of thick and thin filaments, which provide the myocyte with its characteristic striated pattern. The thick filaments consist of interdigitating molecules of myosin and the myosin-binding proteins, while the thin filaments consist of monomers of α -actin, as well as the regulatory proteins, α -tropomyosin and troponins T, I, and C. A third filament within the myofibril is the giant protein titin.

Cardiac myocytes are joined at each end to adjacent myocytes at the intercalated disc. The intercalated disc contains gap junctions (containing connexins) which mediate electrical conduction between cells and mechanical junctions, composed of adherens junctions and desmosomes. The myocyte also contains an extensive and complex network of proteins, which links the sarcomere with the sarcolemma and in turn, with the extracellular matrix. This highly organised cytoskeleton provides support for subcellular structures and transmits mechanical and chemical signals within and between cells, by activating phosphorylation cascades.^{20–22}

Myocardial activation is dependent on the phenomenon of excitation-contraction coupling. This is mediated through the release of calcium into the myocyte from the extracellular space, but more importantly from intracellular stores, particularly from an intracellular network of membranes, the sarcoplasmic reticulum. It appears that the generation of an action potential facilitates the influx of calcium from the extracellular space, through the so-called L-type calcium channels, which are particularly concentrated in specialised areas of the sarcolemma (transverse tubules) and which invaginate into the cell to reach its interior, close to receptors on the surface of the sarcoplasmic reticulum (the so-called ryanodine receptors). The increase in the intracellular concentration of calcium, which results from its influx from the extracellular space, triggers further release of calcium from the sarcoplasmic reticulum. The calcium activates myocardial contraction through its interaction with regulatory proteins on the myofibrils. Conversely, diastole is heralded by the reuptake of calcium into the sarcoplasmic reticulum through the activation of an energy-dependent mechanism which resides with the so-called sarcoplasmic reticulum calcium ATPase, which itself is regulated by a number of stimulatory and inhibitory proteins, in particular the inhibitory protein phospholamban.

The ambient level of myocardial activation is modulated by the actions of catecholamines through their interaction with specific receptors on the surface on the myocyte. Stimulation of these receptors invokes a series of complex intracellular phosphorylation cascades, which modulate not only the rate of influx of calcium from the extracellular space, but also the release and reuptake of calcium from the sarcoplasmic reticulum and the affinity of the myofibrillar proteins for calcium.

Central to the function and homeostasis of the cardiomyocyte is the mitochondrion. As the heart is the organ in the body with the highest oxygen uptake rate and an enormous demand for the continuous synthesis of adenosine triphosphate by oxidative phosphorylation, cardiac myocytes have a very high density of mitochondria. This central role for the mitochondrion as the power source for the cell and its position as the major site for the transformation of energy within the myocyte has been well-established. Energy is stored in the form of high-energy phosphate bonds in adenosine triphosphate. The free energy necessary for the formation of the adenosine triphosphate by the phosphorylation of adenosine diphosphate is derived from the oxidation of nicotinamide adenine dinucleotide by the electron transport chain.

As well as playing a central role in the metabolism of oxygen, it is also now recognised that the mitochondrion plays a crucial role in both apoptosis and necrosis, through its so-called permeability transition pores. The mitochondrion contains all the necessary machinery for apoptosis and is now acknowledged to be a key determinant in whether a myocyte will live or die after a pathological insult.²³ Central to this determination is the role of reactive oxygen species, generated by the diversion of electrons from the electron transport chain. While it has been long established that excessive levels of superoxide may result in damage to biological molecules, for example the sarcolemma and intracellular proteins, it is also established that reactive oxygen species play a central signalling role within the cell, which may not only regulate the key metabolic pathways within the cell, but also prevent apoptosis and cellular necrosis. It is clear therefore that the mitochondrion and reactive oxygen species play a central role as executioner or saviour in determining the viability of the cardiomyocyte.^{24,25}

The Cardiac Myocyte in Cardiac Failure

Having considered the basic physiology of the cardiac myocyte, it is of interest to consider that any of these elements, the myofibrils, the sarcolemma, the gap junctions, the cytoskeleton, the mechanism of excitation-contraction coupling, the adrenergic receptors or the mitochondria may contribute to the pathogenesis of cardiac failure. This role may be a primary one, for example the abnormality of the mitochondrion seen in a patient with a so-called mitochondrial cardiomyopathy,²⁶ the abnormality of the key component of the cytoskeleton, dystrophin in the patient with muscular dystrophy²⁷ or the mutation in a sarcomeric protein in a patient with hypertrophic cardiomyopathy.²⁸ Abnormalities of these elements may also occur secondary to a primary insult originating outside the myocyte. They may thus represent the final common pathway in the development of cardiac failure^{29,30} and the maladaptive myocardial response to a host of primary external insults. Thus, the development of cardiac failure secondary to ischaemia-reperfusion injury may be associated with abnormalities of the myocardial mitochondrion, in association with alterations in the expression and function of the adrenergic receptors. In patients with viral myocarditis, changes in the function of the mitochondrion may herald the onset of apoptosis, while enteroviral proteases may

cleave dystrophin, leading to a secondary impairment of its function.²⁹

OTHER ORGANS AND MEDIATORS IN CHRONIC CARDIAC FAILURE

It is now clear that the syndrome of cardiac failure is a multi-system disease, affecting not only the heart, but also many other organs and processes including the sympathetic nervous system, the kidney, the gastrointestinal system and nutrition,³¹ haemopoiesis,^{32,33} the brain,³⁴ and skeletal muscle.³⁵ Of these, we will consider only a few.

The Sympathetic Nervous System

It is now widely acknowledged that activation of the sympathetic nervous system plays a central role in the pathogenesis of congestive cardiac failure. Activation of the sympathetic nervous system occurs early in the course of the disease, even before the onset of symptoms³⁶ and as the syndrome evolves may play both adaptive and maladaptive roles. It appears that in the early stages of the syndrome, before the onset of symptoms, activation of the sympathetic nervous system occurs selectively within the heart³⁷ and kidneys. It has been suggested that this initially selective activation occurs secondary to ventricular dilation, which stimulates the release of natriuretic peptides and activation of the cardiac sympathetic nervous system. This initially adaptive response to ventricular dysfunction may preserve myocardial function. However, with worsening cardiac failure, the onset of symptoms, and as cardiac output and systemic blood pressure falls, this selective activation of the sympathetic nervous system becomes generalised as the high pressure baroreceptors within the heart and the carotid sinus become unloaded.^{38,39}

Although activation of the sympathetic nervous system may play an important role in maintaining cardiac output and arterial blood pressure in the early stages of the condition (adaptive response), with time catecholamines may have detrimental effects. Elevated levels of catecholamines in the plasma⁴⁰ have been shown to correlate with decreased survival, which may be secondary to myocardial hypertrophy or activation of the renin-angiotensin system. Catecholamines are also known to be toxic to the myocyte,⁴¹ through their effects on the intracellular levels of calcium.^{42,43}

Retention of Sodium and Water

From the time that the condition was known as dropsy, retention of salt and water has been recognised to be a prominent feature of cardiac failure. Recent decades have considerably improved our understanding of the mechanisms responsible for the retention of sodium and water, and in particular have highlighted the contributions of activation of the sympathetic nervous system and the renin-angiotensin-aldosterone system, as well as the role of arginine vasopressin, aquaporins, and the natriuretic peptide systems.⁴⁴

A pivotal trigger in the development of sodium and water retention has been attributed to arterial underfilling, secondary to a reduction in cardiac output. Unloading of the baroreceptors in the arterial tree results in activation of the sympathetic nervous activity, including to the kidneys, where it may not only impact directly on the retention

of sodium and water, but may also stimulate the renin-angiotensin system.⁴⁵ Activation of the sympathetic nervous system within the supraoptic and paraventricular nuclei of the hypothalamus results in the release of vasopressin which further contributes to the retention of water by the kidney.

Activation of the renin-angiotensin system occurs early in the evolution of cardiac failure, with levels of renin within the plasma being observed before the onset of symptoms in patients with subclinical dysfunction of the left ventricle. Angiotensin plays a number of roles in the pathogenesis of cardiac failure. Although its synthesis is stimulated by sympathetic stimulation, angiotensin, in turn, enhances activity of the sympathetic nervous system, through a positive feedback loop. Angiotensin II has important vasoconstrictor properties as well as contributing directly to the development of cardiac hypertrophy and fibrosis.⁴⁶ Angiotensin II plays a central role in retaining sodium and water, through its direct effects on the tubular absorption of sodium, as well as indirectly through its effects of the secretion of aldosterone by the adrenal gland.

The natriuretic peptide system which is activated in cardiac failure is also important in the retention of sodium and water. In normal subjects, natriuretic peptides increase the rate of glomerular filtration and sodium excretion by the kidney. Although the secretion of natriuretic peptides is increased in the early stages of the evolution of cardiac failure, it is now known that cardiac failure is associated with considerable resistance to their actions.^{44,47} This resistance to natriuretic peptides which may contribute substantially to the retention of sodium has been attributed to a number of factors, including a downregulation of the receptors for natriuretic peptides in the kidney, secretion of natriuretic peptide which is biologically inactive or its enhanced degradation by the enzyme neutral endopeptidase or by phosphodiesterase.⁴⁸

While for decades, it was thought that vasopressin contributed little to the retention of water in patients with cardiac failure, it has been shown more recently that vasopressin through its actions on aquaporins within the collecting duct of the renal tubule may play a central role.⁴⁹ In animal models of congestive cardiac failure, the expression of aquaporin-2 is increased⁵⁰ and in clinical studies, antagonists of vasopressin may result in a dose-related increase in water excretion.⁵¹

TREATMENT OF CHRONIC CARDIAC FAILURE

The treatment of chronic cardiac failure has changed greatly over the years. Not surprisingly, once it was recognised that the cause of congestive cardiac failure was a failing pump, treatment strategies were directed toward making the pump work better. For centuries, the only treatment available for cardiac failure was digitalis. First described in his classic monograph in 1785, Withering praised the efficacy of the leaves of the common foxglove plant.⁵² With the advent of the understanding of the complex neurohormonal syndrome now recognised as cardiac failure, strategies for the treatment of cardiac failure have changed from that of increasing pump function to that of decreasing the maladaptive neurohormonal stimulation associated with cardiac failure. In fact, no positive inotropic medication has ever been shown to increase survival in cardiac

failure. The following discussion will focus on the current strategies for the treatment of cardiac failure, particularly as it relates to children. The development of an evidence base for the treatment of chronic cardiac failure is somewhat unique in that no drug has ever been developed solely for the treatment of cardiac failure; angiotensin converting enzyme inhibitors and β -adrenergic receptor blockers were both developed initially for the treatment of hypertension.

The use of the term cardiac failure in children can have many different implications. Patients with large left-to-right shunts with pulmonary over-circulation and tachypnea can be described as being in cardiac failure, despite the fact that ventricular performance is usually normal. Surgical outcomes for the treatment of these types of lesions, even in the smallest and youngest of infants, are now good enough to recommend early surgical correction. Thus, with few exceptions, long-term medical management of these structural lesions is unnecessary and will not be discussed in this chapter. Similarly, medical management of symptomatic valvar regurgitation is no longer routinely considered, since surgical correction is the treatment of choice in most cases. Finally, an evidence base is lacking for the treatment of patients with cardiac failure with preserved systolic function (also called diastolic cardiac failure), particularly in children. Because of this paucity of data, this type of cardiac failure will not be discussed. The remainder of this chapter will focus on the treatment of cardiac failure in children and adults as a result of decreased systemic ventricular dysfunction.

Digoxin

As stated above, digitalis has been the mainstay of chronic cardiac failure treatment for centuries. Even before physicians really knew what actually caused oedema, shortness of breath and/or anasarca, it was known that digitalis improved these maladies in addition to normalising irregular heart rates. Once it was known that this syndrome of oedema, shortness of breath, anasarca and irregular heart rate was due to poor cardiac function, then the use of digoxin as a treatment for cardiac failure needed to be studied more carefully. The mechanism of action is through inhibition of the sodium-potassium pump both within the heart and elsewhere. Within the heart such inhibition results in increased contractility; while outside, it reduces the sympathetic outflow from the central nervous system⁵³ and the release of renin by the kidney.⁵³ Several studies have helped define the role of digoxin in the treatment of cardiac failure.^{54–56} These studies showed that, although digoxin does not improve survival in cardiac failure, it does indeed improve symptoms. Current recommendations in adults are that physicians can consider adding digoxin in patients with persistent symptoms of cardiac failure during therapy with diuretics, and an angiotensin converting enzyme inhibitor or angiotensin receptor blocker and a β -adrenergic blocker.⁵⁷ Toxicity from digoxin was common when serum levels exceeded 2.0 ng/mL and so early practice was to maintain levels to just below toxicity to achieve maximal benefit. More recent retrospective analyses of this and other studies suggest that lower doses may be better than higher doses.^{58,59} There is now increasing evidence that lower levels of digoxin are safer and at least as efficacious as higher levels for the treatment of chronic cardiac failure.

Since digoxin only appears to be helpful in the treatment of symptomatic cardiac failure, there is little if any role for it in the treatment of asymptomatic cardiac failure. In the most recent recommendations of the American Heart Association and the American College of Cardiology, digoxin is only recommended in the treatment of symptomatic cardiac failure, and actually contra-indicated in asymptomatic patients, unless atrial fibrillation is present.⁵⁷

The indications for the use of digoxin in paediatric cardiac failure are less clear. The most recent recommendations of an expert group of paediatric cardiologists recognise that there is little data to support or refute its use in paediatric cardiac failure.⁶⁰ In patients with left-to-right shunts such as ventricular septal defects, the data is conflicting as to whether digoxin has any beneficial haemodynamic effects.^{61–63} In one study, digoxin acutely worsened haemodynamics in children with cardiac failure due to left-to-right shunts.⁶⁴ There is no data to either support or refute the use of digoxin in children with cardiac failure due to ventricular dysfunction. Thus, in the absence of pediatric data, one can consider using the recommendations for digoxin in adult cardiac failure, with the caveats that these extrapolations become much less justifiable in the extremely young child or in the child with systemic ventricular dysfunction whose systemic ventricle is not of a left ventricular morphology. Major side effects include arrhythmias and gastrointestinal and neurological symptoms. Digoxin interacts with many medications (e.g., amiodarone, carvedilol, verapamil, spironolactone, flecainide, propafenone), and interactions should be explored before instituting digoxin therapy.

Diuretics

Although diuretics have never been shown (and possibly never will) to improve survival in cardiac failure, their use is considered important because of the need for anti-congestive measures in the treatment of cardiac failure. This is based largely on the significant symptomatic relief and haemodynamic improvement seen in patients with congestive cardiac failure treated with diuretics. A large number of diuretics are available, including those that act on the renal loop of Henle (loop diuretics) and those that act in the distal tubules of the kidney (thiazides). Potassium sparing diuretics will be discussed below in the section on aldosterone antagonists. Diuretics interfere with the retention of sodium in the kidney, and water follows this increased excretion of sodium passively. This causes a decrease in filling pressure of the ventricle and a reduction in right-sided (e.g., hepatic) and left-sided (e.g., pulmonary) congestion. The most common side effects are depletion of electrolytes and fluid (e.g., hyponatremia, hypokalemia), elevated urea levels in the plasma and even hypotension if excessive diuresis takes place. There is some evidence from retrospective analyses of previous trials that diuretics which do not result in sparing of potassium may actually be harmful in the treatment of cardiac failure, but further prospective studies are needed to confirm this.^{65,66}

Inhibitors of the Renin-Angiotensin System

As stated above, the primary thrust of the treatment of cardiac failure over the last quarter century has been directed toward inhibition of the initially adaptive and ultimately

maladaptive neurohormonal response to low cardiac output. The most studied and effectively inhibited neurohormonal system has been the renin-angiotensin system. Inhibitors of the angiotensin converting enzyme have been studied in many large, prospective randomised trials in adults with cardiac failure, in which more than 7000 adults have been enrolled.^{67–70} These studies have conclusively demonstrated that these agents improve symptoms and survival in adults with cardiac failure, and delay the onset of symptoms in those asymptomatic patients with decreased systolic ventricular function. These drugs work through the inhibition of angiotensin converting enzyme which inhibits the conversion of angiotensin I to angiotensin II, a potent vasoconstrictor. Angiotensin converting enzyme is identical to kininase II, thus having an additional action of increasing bradykinin levels. This is thought to be responsible for the relatively frequent side effect of cough seen in some patients who take these agents. They also reduce afterload, preload and systolic mural stress. Angiotensin converting enzyme inhibitors are currently recommended for all adult patients with symptomatic cardiac failure and for those with a history of symptomatic cardiac failure,⁵⁷ unless the patient is intolerant of them.

The data on the efficacy of angiotensin converting enzyme inhibitors in children with cardiac failure is less robust than in adults. Many small studies from the 1980s and 1990s suggested that they may be beneficial in children with cardiac failure due to left-to-right shunts.^{71–73} A few small retrospective reports also suggested a possible benefit from them in children with decreased systolic ventricular function.^{74,75} One prospective, randomised trial compared the effects of enalapril with placebo in children who had undergone the Fontan operation. The primary end-point was exercise capacity, and no difference was found between the two groups after 10 weeks of therapy. In fact, the mean percent change from rest to maximal exercise was significantly decreased in the enalapril group compared to placebo.⁷⁶ Another study compared two groups of post-operative patients at two different hospitals, one receiving post-operative angiotensin converting enzyme inhibitors and one not. Those receiving inhibitors had a decreased duration and amount of pleural drainage.⁷⁷

Angiotensin II receptor blockers have been shown to be beneficial in the treatment of cardiac failure in adults, but not superior to angiotensin converting enzyme inhibitors. Thus, angiotensin receptor blockers are currently recommended for the treatment of cardiac failure in adults, primarily those who are intolerant to angiotensin converting enzyme inhibitors. There is very little experience with angiotensin receptor blockers in children. Studies of angiotensin converting enzyme inhibitors and angiotensin receptor blockers in young adults with congenital heart disease and cardiac failure due to dysfunction of a systemic right ventricle have failed to show a clear benefit.^{78,79}

Beta-Blockers

Waagstein and colleagues first reported the beneficial effects of β -blockade in a small group of adults with cardiac failure in 1975.⁸⁰ Many small studies over the next 20 years suggested some benefit from metoprolol, bisoprolol, and carvedilol in adults with stable, chronic cardiac failure.^{80–82} However, it was not until 1996, that two large, prospective,

Figure 15-5 Mortality rates at 6 months (deaths per 100 patients randomised). (From Bristow MR, Gilbert EM, Abraham WT, et al: Carvedilol produces dose-related improvements in left ventricular function and survival in subjects with chronic heart failure. MOCHA Investigators. *Circulation* 1996;94:2807–2816.)

randomised trials of carvedilol conclusively demonstrated that β -blockers improve symptoms, survival, and ventricular remodeling in adults with mild-to-moderate cardiac failure^{81,82} (Fig. 15-5).

Subsequent studies have shown that other β -blockers, the long-acting metoprolol and bisoprolol, have similar effects to carvedilol in adults with mild-to-moderate cardiac failure.^{83,84} Subsequently, carvedilol was also shown to improve survival in adults with severe cardiac failure⁸⁵ (Fig. 15-6). Based on these studies, β -blockers are now recommended for all adults with stable cardiac failure due to reduced left ventricular ejection fraction unless they have a contraindication to their use or have been shown to be intolerant to these drugs.⁵⁷

Not all β -blockers are equally effective in the treatment of cardiac failure. In one large, randomised trial, bucindolol failed to show a survival benefit in adults with cardiac

Figure 15-6 Analysis of time to death in patients receiving either placebo or carvedilol in the COPERNICUS trial. The 35% lower risk in the carvedilol group was significant: $P = 0.00013$ (unadjusted) and $P = 0.0014$ (adjusted). (Used with permission from Packer M, Fowler MB, Roecker EB, et al: Effect of carvedilol on the morbidity of patients with severe chronic heart failure: Results of the carvedilol prospective randomized cumulative survival [COPERNICUS] study. *Circulation* 2002;106:2194–2199.)

Figure 15-7 Mortality rates from all causes in patients treated with either carvedilol or metoprolol in the COMET trial. Mortality was significantly lower in the carvedilol group (34%) than the metoprolol group (40%). (Used with permission from Poole-Wilson PA, Swedberg K, Cleland JG, et al: Comparison of carvedilol and metoprolol on clinical outcomes in patients with chronic heart failure in the Carvedilol or Metoprolol European Trial [COMET]: Randomised controlled trial. *Lancet* 2003;362:7–13.)

failure.⁸⁶ The reason for this is unclear, but may be at least in part due to some interesting pharmacogenomic reasons that will be discussed later in this chapter. One comparison of metoprolol and carvedilol demonstrated improved survival after carvedilol compared to after metoprolol⁸⁷ (Fig. 15-7). This may be due to the broader actions of carvedilol, affecting the β -1, β -2, and α -1 receptors compared to metoprolol which is selective for the β -1 receptor.⁸⁸

The initial reports of the use of β -blockers in children with cardiac failure suggested possible benefit of metoprolol in some children with cardiac failure due to anthracycline toxicity, dilated cardiomyopathy or congenital heart disease.^{89–91} Since the FDA approved the use of carvedilol in adults, many small (mostly retrospective) studies have reported its potential benefit in children with cardiac failure due to systemic ventricular dysfunction.^{92–97} However, the only multi-centre, prospective, randomised, double-blind trial of carvedilol in children with cardiac failure due to systemic ventricular dysfunction failed to detect a benefit of carvedilol over placebo in a composite end-point of clinical outcomes.⁹⁸ The half-life of carvedilol in children is shorter than in adults.⁹⁴ Thus, higher doses may be needed. Also, carvedilol increases levels of digoxin, so one needs to monitor and probably decrease doses of digoxin in children started on carvedilol.⁹⁹ Thus, it is likely that certain children with cardiac failure may benefit from β -blocker therapy, but the indications and dosing need to be defined.

Cardiac Resynchronisation Therapy

Patients with a left bundle branch block have delayed activation and contraction of the free wall of the left ventricle. It has long been recognised that this may alter regional loading conditions, myocardial blood flow, and myocardial metabolism.¹⁰⁰ There are regional alterations in gene expression and production of proteins involved with mechanical function and stress which lead to derangements of both contractile and non-contractile elements, resulting in ventricular remodeling, dilation, and pump failure. Early studies demonstrated that cardiac resynchronisation therapy

resulted in improvements in functional class, quality of life, distances walked in 6 minutes, and ejection fraction.¹⁰¹ More recently, resynchronisation therapy has been shown to improve survival in cardiac failure,¹⁰² thus making it a class 1 recommendation for the treatment of adults with left ventricular ejection fraction lower than 35%, sinus rhythm, QRS duration of at least 120 msec, with moderate-to-severe cardiac failure on maximal cardiac failure medications.⁵⁷

The knowledge base for cardiac resynchronisation therapy in children is small. Some series have demonstrated its feasibility in children with a resultant decrease in QRS duration and possible beneficial effects on ventricular reverse remodelling.^{103,104} In the largest report to date, Dubin and colleagues reviewed their experience with this form of treatment in 103 children with cardiac failure due to dilated cardiomyopathy, congenital heart disease, or complete heart block.¹⁰⁵ The average change in left ventricular ejection fraction reported after treatment was about 13%, although there was no difference in this measurement between the three groups. The only discernible characteristic predictive of response versus no response was a lower ejection fraction before treatment (24% vs. 32%). However, the incidence of side effects was significant. Three percent of patients died early and 2% later. Five percent of patients had complications related to the coronary sinus electrode. Thus, as with virtually all other treatments for cardiac failure in children, the indications for resynchronisation therapy are unclear, and their potential risk-benefit ratio is still to be determined.

Treatments Primarily Aimed at Reducing Sudden Death

Mortality in patients with cardiac failure is related either to terminal end-organ failure or sudden death. While the treatment options discussed in this chapter, until now, aim to maintain stability with the patient's cardiac failure, recently there has been increasing interest in the use of therapies which aim primarily to reduce the risk of sudden death in this group of patients. As a result, implantable cardioverter-defibrillators are now widely recommended in the treatment of selected adults with chronic, stable cardiac failure.⁵⁷ Early studies with these devices suggested benefit in those patients who had suffered an aborted sudden death episode (secondary prevention)^{106–108} although more recent, randomised trials have shown clear benefit in the primary prevention of sudden death in adults with a left ventricular ejection fraction less than 35%, and mild-to-moderate cardiac failure (Fig. 15-8).¹⁰⁹

A meta-analysis of 13 studies in pediatric dilated cardiomyopathy demonstrated a 27% incidence of sudden death in children who died of this disease (Table 15-1).¹¹⁰ Thus, appropriate application of cardioverter-defibrillator therapy to children with cardiac failure could clearly save lives, although there is a paucity of data on their use in children. Although not proven, possible indications include children with cardiac failure and the following: an aborted sudden death episode, severe, symptomatic cardiomyopathy awaiting heart transplantation, after heart transplantation with severe graft vasculopathy awaiting retransplantation.^{111,112} Many of the technical challenges described above for resynchronisation therapy in children applies to implantable cardioverter-defibrillators.

Figure 15-8 Estimates of death from any cause in the SCD-HeFT trial. (From Bardy GH, Lee KL, Mark DB, et al: Amiodarone or an implantable cardioverter-defibrillator for congestive heart failure. *N Engl J Med* 2005;352:225–237.)

Figure 15-9 Survival to death or transplantation from time of presentation: overall, with 95% CI (A), with patients grouped by age at presentation (B), with patients grouped by presence or absence of familial cardiomyopathy (C), and with patients grouped by presence or absence of lymphocytic myocarditis on endomyocardial biopsy (D). (Used with permission from Daubeney PE, Nugent AW, Chondros P, et al: Clinical features and outcomes of childhood dilated cardiomyopathy: Results from a national population-based study. *Circulation* 2006;114:2671-2678.)

OUTCOME IN PAEDIATRIC CARDIAC FAILURE

There is little data which determines outcomes for all children with a diagnosis of cardiac failure. Obviously, outcome will depend upon a large number of factors, including the cause for the cardiac failure, its severity at the time of presentation and the age and possibly gender of the patient, as well as other factors. With the advent of new medications and pacing interventions, this outcome is hopefully improving over time. Preliminary data from a large prospective, multi-centre trial suggest that more than 50% of children with cardiac failure, who have been stabilised on ACE inhibitors and other oral medications for at least one month, will show improvement over an 8-month period of evaluation.⁹⁸ More long-term evaluation of outcomes is available for children with dilated cardiomyopathy, many, but not all, of which have some degree of cardiac failure.^{113,114} In these studies, risk factors for death or transplantation include older age, presence of cardiac failure, worse left ventricular function (fractional shortening or ejection fraction), failure to increase left ventricular function during follow-up, familial cardiomyopathy, moderate-to-severe mitral regurgitation, and ventricular arrhythmias (Fig. 15-9).

This interesting review article summarises for clinicians the transition from the initially selective, regional and adaptive activation of the sympathetic nervous system to a generalised activation of all the neurohumoral systems.

- Re RN: Mechanisms of disease: Local renin-angiotensin-aldosterone systems and the pathogenesis and treatment of cardiovascular disease. *Nat Clin Pract* 2004;1:42-47.

Accumulating evidence has made it clear that not only does the renin-angiotensin-aldosterone system exist in the circulation, but it is also active in many tissues—and likely within cells as well. These local systems affect the concentrations of angiotensin II in tissues and appear to be associated with clinically relevant physiologic and pathophysiologic actions in the cardiovascular system and elsewhere. The evidence in support of this possibility is reviewed in this article.

This editorial explores the hypothesis that clinically important differences exist among the many adrenergic blockers which might be used in the treatment of chronic cardiac failure.

- Cleland JG, Daubert JC, Erdmann E, et al: The effect of cardiac resynchronization on morbidity and mortality in heart failure. *N Engl J Med* 2005;352:1539–1549

This study randomised patients with class III or IV cardiac failure to receive medical therapy alone or with cardiac resynchronisation. Cardiac resynchronisation improved symptoms and the quality of life and reduced complications and the risk of death. These benefits were in addition to those afforded by standard pharmacologic therapy.

- Bardy GH, Lee KL, Mark DB, et al: Amiodarone or an implantable cardioverter-defibrillator for congestive heart failure. *N Engl J Med* 2005;352:225–237.

In this study patients with class II or III cardiac failure and a left ventricular ejection fraction of less than 35% were treated with either conventional therapy alone, conventional therapy plus amiodarone or conventional therapy plus a conservatively programmed, shock-only, single-lead implantable defibrillator. Amiodarone was found to have no effect on survival, whereas the defibrillator reduced overall mortality by 23%.

- Towbin JA, Lowe AM, Colan SD, et al: Incidence, causes, and outcomes of dilated cardiomyopathy in children. *JAMA* 2006;296:1867–1876.

This paper provides data on children who presented to 89 centres with dilated cardiomyopathy. The 1- and 5-year rates of death or transplantation were 31% and 46% respectively. Risk factors for death were older age, congestive cardiac failure, and the fractional shortening of the left ventricle. It was not possible to identify a cause for the disease in most children.

Transplantation of the Heart, and Heart and Lungs

ANNE I. DIPCHAND and ELIZABETH D. BLUME

The first transplantation of a human heart was performed in South Africa in 1966.¹ By the end of the 1970s, transplantation was established as an effective therapy for end-stage cardiac failure. Over the next 25 years, improvements in donation and preservation of organs, selection of patients, post-operative management, and treatment of rejection have resulted in improved survival following transplantation in both adults and children. Consequently, orthotopic transplantation of the heart is now widely accepted as an important part of management for infants and children with severe forms of congenital cardiac disease and cardiomyopathy.

PATTERNS OF REFERRAL AND DEMOGRAPHICS OF TRANSPLANTATION OF THE HEART DURING CHILDHOOD

The factors affecting referral and listing of patients for cardiac transplantation are complex, but will include the availability and outcomes of alternative surgical strategies, availability of specific expertise, the patterns of referral to an individual centre, as well as societal and individual beliefs. Analysis of the natural history and outcomes must take all these factors into account. Besides reports from single centres, there are two main sources of data on outcomes for children following listing for transplantation and subsequent to transplantation. The registry of the International Society of Heart and Lung Transplantation² is an international registry, to which referral is voluntary except in the United States of America, where federal mandate requires

all data from the United Network of Organ Sharing to be shared with the database of the International Society. The second source is the Pediatric Heart Transplant Study, a voluntary, research-based and event-driven multi-centric registry. It was established in 1993 in order to capture data relative to outcomes³ from the Pediatric Heart Transplant Study. This source currently includes 3454 patients listed for transplantation, of whom 2452 patients underwent transplantation between January 1, 1993, and December 31, 2007. The data is supplied by 33 centres within North America and the United Kingdom.

According to the 10th annual report² of the International Society of Heart and Lung Transplantation registry, presented in 2007, the number of transplantations in children performed each year has remained stable, at approximately 375 to 400, since the mid-1990s, as has the distribution of ages (Figs. 16-1 and 16-2). Geographical differences exist worldwide. For example, teenagers account for half of the recipients in Europe and other areas of the world, whereas in North America more infants undergo transplantation (Fig. 16-3).

The underlying diagnoses prior to transplantation have changed over time. In infants younger than 1 year of age, congenital cardiac disease has remained the commonest underlying diagnosis, though the proportion of infant recipients with cardiomyopathy has almost doubled over time, increasing from one-sixth to one-third (Fig. 16-4). Cardiomyopathy remains the main diagnosis amongst those aged from 1 to 10 years and amongst adolescents (Figs. 16-5 and 16-6). Indications for transplantation also

Figure 16-1 Annual age distribution of recipients of cardiac transplantation during childhood. (From the registry of the International Society of Heart and Lung Transplantation. J Heart Lung Transplant 2007;26:796-807.)

NOTE: This figure includes only the heart transplants that are reported to the ISHLT Transplant Registry. As such, this should not be construed as evidence that the number of hearts transplanted worldwide has increased or decreased in recent years.

show geographic variation, with congenital cardiac disease and retransplantation both more common in North America compared with Europe (Fig. 16-7).²

OUTCOMES

Overall Survival

Overall survival for children listed for heart transplantation, including deaths prior to and after transplantation, as listed in the Pediatric Heart Transplant Study is 74%, 66%, and 59% at 1, 5, and 10 years respectively.⁴ Overall survival from the time of listing is higher for patients with a diagnosis of cardiomyopathy compared to those with congenitally malformed hearts (Fig. 16-8).⁵ There is an effect of era, with improved survival at all times after listing in the period from 2003 through 2006 (Fig. 16-9).⁴

Mortality while Awaiting Transplantation

Death whilst waiting for transplantation reflects a combination of availability of donor organs, the medical state of the recipient, the underlying diagnosis, and the blood group. While modifying availability of organs is difficult, knowledge of the other factors that influence mortality during the period of waiting plays an important role in decision-making regarding appropriate timing for listing a patient for transplantation.

Figure 16-8 Actuarial survival curve in children aged from 0 to 18 years who underwent primary cardiac transplantation between January 1, 1993, and December 31, 2006, stratified by diagnosis, with all patients having cardiomyopathy (CM) compared with all other patients. Analysis includes death after transplantation. (Data from the registry of the Pediatric Heart Transplant Study.)

Data from the Pediatric Heart Transplant Study for the period between 1993 and 2006 demonstrates mortality for all listed patients whilst waiting of 17% at 1 year.⁴ Unsurprisingly, mortality during the period of waiting varies according to the state of the patient, with those listed

Figure 16-9 Actuarial survival curve in children aged from 0 to 18 years who underwent primary cardiac transplantation between January 1, 1993, and December 31, 2004, stratified by era. Includes death after transplantation. (Data from the registry of the Pediatric Heart Transplant Study. From Morrow RW, Kirklin JK: Survival after pediatric heart transplantation. In Canter CE, Kirklin JK: Pediatric Heart Transplantation. ISHLT Monograph Series, vol. 2. Philadelphia, Elsevier, 2007, Chap. 8, Fig. 5, p. 129.)

Figure 16-10 Actuarial survival curve in children aged from 0 to 18 years who underwent primary cardiac transplantation between January 1, 1993, and December 31, 2006, stratified by diagnosis, cardiomyopathic (CM) patients being compared with all others. This graph reflects overall wait-list mortality as patients are censored at the time of transplantation. (Data from the registry of the Pediatric Heart Transplant Study.)

Figure 16-11 Kaplan-Meier survival curve out to 20 years after cardiac transplantation in childhood stratified by age at the time of transplantation. (From the registry of the International Society of Heart and Lung Transplantation. J Heart Lung Transplant 2007;26:796–807.)

at level 1A in the system used by the United Network for Organ Sharing having a mortality of 21%, compared to 7% for those listed as level 1B or 2.⁴ A diagnosis of cardiomyopathy carries a lower mortality during this period of waiting than do other diagnoses (Fig. 16-10).⁵ Blood group O, in contrast, has been associated with a higher risk of death.⁶ The mortality for infants during the period of waiting, at from 25% to 30%, has consistently been higher than that reported for older patients.⁷⁻⁹

Survival after Transplantation

Data from the registry of the International Society of Heart and Lung Transplantation shows that survival after transplantation in the most recent era is 80%, 68%, and 58% for 1, 5, and 10 years respectively.² The survival after 20 years, while clearly reflecting transplantation during an earlier era, is 40% (Fig. 16-11).² Looked at a different way, the same data shows a half-life for transplantation, defined as the time to 50% survival without death or retransplantation, of 15.8 years for those aged less than 1 year at transplantation, 14.2 years for those aged from 1 to 10 years, and 11.4 years for those older than 11 years. These differences are even more marked when conditional survival is examined, excluding mortality related to the procedure itself (Figs. 16-12 and 16-13). Infants and neonates are relatively protected from later complications, while adolescents, who have lower mortality over the short term, are at increased risk of death or the need for retransplantation during long-term follow-up. Data from the Pediatric Heart Transplant Study is similar, showing that overall survival is generally good, with survival at 1 and 5 years of 85% and 75%.⁴

When survival is analysed by era, significant improvements are revealed in the results of transplantation of the heart during childhood, primarily related to a reduction in mortality immediately subsequent to transplantation (Fig. 16-14). Conditional survival for the different age groups within the period from 1999 through 2005 amplifies the difference between infants and adolescents, with infants having a conditional survival at 6 years of greater than 85%, while that of adolescents is approximately 65% (Fig. 16-15).

The diagnosis before transplantation also modifies survival. There is a significantly higher early mortality for

Figure 16-12 Conditional Kaplan-Meier survival, conditional on survival to 1 year subsequent to cardiac transplantation, stratified by age at transplantation. (From the registry of the International Society of Heart and Lung Transplantation. *J Heart Lung Transplant* 2007;26:796–807.)

Figure 16-13 Conditional Kaplan-Meier survival conditional on survival to 5 years subsequent to cardiac transplantation stratified by age at transplantation. (From the registry of the International Society of Heart and Lung Transplantation. *J Heart Lung Transplant* 2007;26:796–807.)

Figure 16-14 Kaplan-Meier survival curve out to 20 years after cardiac transplantation during childhood stratified by era. (From the registry of the International Society of Heart and Lung Transplantation. *J Heart Lung Transplant* 2007;26:796–807.)

Figure 16-15 Conditional Kaplan-Meier survival conditional on survival to 1 year after cardiac transplantation for the most recent era from 1999 through 2005 stratified by age at transplantation. (From the registry of the International Society of Heart and Lung Transplantation. *J Heart Lung Transplant* 2007;26:796-807.)

patients with congenitally malformed hearts, compared to those transplanted for cardiomyopathy (see Fig. 16-8), with a recent analysis of patients transplanted for dilated cardiomyopathy showing an overall survival of 73% at 10 years.⁵

Risk Factors for Death

The risk factors for death in the first year following transplantation of the heart during childhood are outlined in

TABLE 16-1

RISK FACTORS FOR 1-YEAR MORTALITY IN CHILDREN WITH A TRANSPLANTED HEART

Variable	N	Relative Risk	P Value	95% Confidence Interval
Congenital diagnosis, age = 0, on ECMO	51	5.66	<0.0001	3.54-9.06
Congenital diagnosis, age >0, on ECMO	48	4.30	<0.0001	2.58-7.14
Congenital diagnosis, age >0, no ECMO	710	2.23	<0.0001	1.70-2.91
Congenital diagnosis, age = 0, on PGE	201	2.12	0.0003	1.40-3.20
Retransplant	179	1.91	0.0029	1.25-2.92
Congenital diagnosis, age = 0, no PGE or ECMO	336	1.90	0.0004	1.33-2.70
On ventilator	581	1.45	0.0033	1.13-1.87
Year of transplant: 1995-1996 vs. 1999-2000	547	1.43	0.0191	1.06-1.94

ECMO, extracorporeal membrane oxygenation; PGE, prostaglandin E1. Data from the registry of the International Society of Heart and Lung Transplantation. *J Heart Lung Transplant* 2007;26:796-807.

Table 16-1. They include a diagnosis of congenital cardiac disease, need for extracorporeal mechanical support, mechanical ventilation before transplantation, and retransplantation.² Risk factors for mortality during the first 5 years are similar (Table 16-2), but female gender of both the recipient and the donor become additional risk factors.²

Causes of Death

The causes of death reported to International Society of Heart and Lung Transplantation registry, stratified by time after transplantation, are summarised in Table 16-3.² Similarly, the data from the Pediatric Heart Transplantation Study, outlining the causes and proportions of deaths within the first 5 years after transplantation, are summarised in Table 16-4. Rejection, infection, failure of the primary graft, and sudden cardiac death are the major causes of death in children within the first 5 years.¹⁰⁻¹² Graft vasculopathy remains the leading cause of death in the longer term. This, combined with failure of the graft and acute rejection, accounted for about seven-tenths of deaths between 5 and 10 years after transplantation.

INDICATIONS AND CONTRAINDICATIONS TO TRANSPLANTATION

Assessment Prior to Transplantation

Careful assessment prior to transplantation is required in order, first, to identify indications for transplantation, second, to identify potentially reversible causes of end-stage heart failure and optimise management, and third, to identify confounding factors or contraindications that may preclude candidacy for transplantation. The general components required for a comprehensive

TABLE 16-2

RISK FACTORS FOR 5-YEAR MORTALITY IN CHILDREN WITH A TRANSPLANTED HEART

Variable	N	Relative Risk	P value	95% Confidence Interval
Congenital diagnosis, age = 0, ECMO	21	3.11	0.0020	1.51-6.39

assessment prior to transplantation are outlined in [Box 16-1](#). In addition to the assessment of the heart, consultation from an interdisciplinary team, including social workers, psychiatrists, physiotherapists, occupational therapists, specialists in adolescent medicine, and key medical services including nephrology and anaesthesia, are critical to the process. For example,

renal and/or hepatic dysfunction has been associated with a reduction in intermediate and long-term survival, and must therefore be integrated into the assessment of risk for child and parents. Psychosocial assessment of the entire family is paramount. This is especially important when assessing adolescents, given the increasing awareness of the impact of non-compliance and risk-taking behaviours on survival of both the graft and the patient.¹³

Indications

There are no absolute indications for transplantation of the heart during childhood given the wide variability in cardiac diagnoses and pathophysiology. Indications can

BOX 16-1

General Components of the Assessment Prior to Transplantation

- Echocardiogram
- Cardiac catheterisation (haemodynamics, anatomy)
- MRI/MRA or CT angiography (anatomy)
- Exercise test
- Vascular ultrasound
- Blood group
- HLA antibody testing
- Chemistry
 - Renal function
 - Liver function
 - Lipid profile
 - Immunoglobulins
- Haematology
- Infectious serologies

be broadly divided into two groups, either life-saving (Box 16-2) or life-enhancing. Life-enhancing indications include treatment of excessive disability, unacceptably poor quality of life, usually in the setting of poor myocardial function, complex unoperated congenital cardiac disease, and failed surgical treatment.

Guidelines for listing adults for cardiac transplantation, based on a comparatively uniform population with cardiac failure and a predictable natural history, have been published by both the American Society of Transplantation¹⁴ and the Canadian Cardiovascular Society.¹ They have limited applicability to transplantation during childhood. Specific guidelines are being developed for the populations of children and adults with congenitally malformed hearts. These strive to identify patients who are at the greatest risk of dying, and who will derive the greatest benefit from transplantation. There are two published consensus reports on the listing of children for cardiac transplantation, but these are predominantly based on the opinions of experts, and their recommendations remain the subject of debate.^{15,16}

Contraindications

The contraindications to transplantation of the heart during childhood included fixed pulmonary hypertension, pulmonary venous atresia or progressive stenosis, and severe hypoplasia of the pulmonary arteries or the thoracic aorta. Other contraindications include irreversible failure of multiple organs, a progressive systemic disease with early mortality independent of cardiac function, active infection, malignancy, multi-specific and high sensitisation to HLA antigens, morbid obesity, diabetes mellitus with end-organ damage, hypercoagulable states, and severe chromosomal, neurological, or syndromic abnormalities. Complicating factors that are no longer considered contraindications to cardiac transplantation include complex congenital cardiac disease, such as abnormalities of atrial arrangement, systemic venous abnormalities, anomalous pulmonary venous drainage without stenosis, and some pulmonary arterial anomalies, previous sternotomy or thoracotomy, reversible pulmonary hypertension, more minor non-cardiac congenital abnormalities, kyphoscoliosis with restrictive pulmonary disease, non-progressive or slowly progressive systemic diseases with

life expectancies into the third or fourth decade such as genetic or metabolic cardiomyopathies, and diabetes mellitus without end-organ damage.

Elevated pulmonary vascular resistance is an independent risk factor for death both early and late after transplantation.^{17,18} The threshold which precludes transplantation is ill-defined, as there is a continuum of increasing risk as pulmonary vascular resistance rises. By convention, a pulmonary vascular resistance of greater than 6 Wood units per meter squared has been considered a contraindication. Intermediate outcomes have been reported nonetheless, for children with pulmonary vascular resistances greater than 6 Wood units, with mortality of 12% and a fall in resistance to less than 4 Wood units when assessed 10 days after transplantation.¹⁸ In another experience, however, one-third of patients with resistances greater than 6 Wood units developed right ventricular failure, with mortality of 15%, with no patient having a resistance less than 6 Wood units developing right ventricular failure.¹⁹ Despite these problems, five-sixths of patients with pulmonary vascular resistances greater than 6 and an indexed pulmonary vascular resistance greater than 9 were successfully transplanted. Both these studies concluded that it is the reactivity of the vascular bed, as opposed to the absolute measure of resistance, which is correlated with outcome. There is a role, therefore, for testing pulmonary vasoreactivity as part of the assessment prior to transplantation.

Accurate assessment of pulmonary vascular resistance and/or vasoreactivity with any diagnosis of functionally univentricular physiology, some complex malformations with variable sources of flow of blood to the lungs, or restrictive cardiomyopathy, nonetheless, may be challenging if not impossible, albeit that the risk of pulmonary hypertension and/or right-sided cardiac failure after transplantation in the population of infants with functionally univentricular hearts is low.²⁰ Timing of listing with a diagnosis of restrictive cardiomyopathy remains controversial. The most recent guidelines recommend listing at, or shortly after, the time of diagnosis due to the limited effect of medical therapies, and concern about the development of a non-reactive pulmonary vascular bed.¹⁶

SPECIAL CONSIDERATIONS

Neonatal Advantage and ABO-incompatible Transplantation

The published data from the registries, and specific institutional experience, increasingly show advantages to successful neonatal transplantation.^{2,21,22} As outlined above, there is consistent evidence from survival curves that infants transplanted at an age of less than 6 months have improved survival when assessed up to 10 years after transplantation in comparison with older age groups (see Figs. 16-11 to 16-13). The reports from the Pediatric Heart Transplant Study show lower rates of rejection and graft vasculopathy in the population of infants.^{23,24} Furthermore, data from Loma Linda University Medical Center shows that infants with hypoplastic left heart syndrome, transplanted at less than 1 month of age have a higher survival rate, 77% at 10 years, and less graft loss, than infants transplanted

BOX 16-2

Life-saving Indications for Heart Transplantation

- End-stage myocardial failure due to
 - Cardiomyopathies or myocarditis
 - Congenital heart disease
 - Post-cardiotomy heart failure
 - Malignant arrhythmias refractory to medical therapy
- Complex congenital heart disease with no options for surgical palliation at an acceptable risk
- Unresectable cardiac tumours causing obstruction or ventricular dysfunction (systolic or diastolic)
- Unresectable ventricular diverticula

from 1 to 6 months of age, only 54% of this latter group surviving at 10 years.^{21,22} The biggest challenge to transplantation during neonatal and infant life remains the availability of donors, which has not changed appreciably over the last decade. Consequently, strategies are being developed to expand the donor pool, or improve utilisation of available organs, one example of which is ABO-incompatible transplantation.

Such transplantation between donors and recipients incompatible for their major blood groups is usually contraindicated because of a high risk of hyperacute rejection mediated via activation of complement. Newborn infants, however, do not produce the isohemagglutinins responsible for the blood groups, and their complement system is not fully developed. It has now been shown heart transplantation across ABO blood groups is possible during infancy, reflecting the immaturity of the infant immune system or even representing the first human example of immune tolerance.²⁵ An advantage of such transplantation is a reduction in deaths during the period of waiting. In an analysis of risk factors relative to the strategy of listing, failure to list for an ABO-incompatible graft and high clinical status emerged as the only factors associated with mortality.²⁶ A strategy to accept ABO-incompatible hearts from donors for transplantation into infants significantly improved the likelihood of transplantation and reduced deaths whilst waiting, at the same time not adversely altering outcomes.

A report has now been compiled of the follow-up over 10 years of the largest cohort of recipients of ABO-incompatible transplantations.²⁷ Survival, the incidence of rejection, graft vasculopathy, and development of lymphoproliferative disorders subsequent to transplantation were no different from the ABO-compatible population followed in the same institution (Table 16-5). It remains to be proven whether there are immunological advantages such as tolerance or accommodation of the graft, but ABO-incompatible transplantation for infants is increasingly being adopted in centres worldwide. The optimal selection criteria for suitability for ABO-incompatible transplantation remain ill defined. In general, the younger the patient the better, but successful transplantation has been performed in recipients as old as 3 years. Antibody-mediated rejection has been

reported, with titres of antibodies as low as 1 to 8, while there are reports of rejection-free survival with titres as high as 1 to 128.²⁸ Assessment should be made by a cardiologist experienced in ABO-incompatible transplantation on an individual basis, taking into account age, blood group, isohaemagglutinin titres, and clinical state.

HLA Sensitisation

Screening panel reactive antibody testing is performed on patients prior to transplantation in an effort to identify the potential presence of anti-HLA antibodies and minimise the risk of antibody-mediated rejection. High panel reactive antibody titres, greater than 10%, are associated with an increased incidence of rejection and reduced survival.^{29,30} Common sensitizing events in children include repair of congenitally malformed hearts, specifically those achieved using homograft material,³¹ and the use of ventricular assist devices.³² There are many reports of transplantation in highly sensitised patients, nonetheless, and/or across a positive crossmatch, with reasonable results over the intermediate term.²⁸ A variety of strategies have been used to lower the titres of antibodies, and/or manage the rejection in sensitised patients. A detailed discussion is beyond the scope of this chapter, but most protocols include plasmapheresis immediately before and after transplantation with, variably, the use of intravenous immunoglobulin, rituximab, cyclophosphamide, and treatment with antineoplastic agents.^{28,33,34}

Mechanical Support as a Bridge to Transplantation

Mechanical circulatory support is increasingly being used as a bridge to transplantation (Fig. 16-16).³⁵ Indications for such support continue to evolve as the availability of devices changes. In general, mechanical support should be considered when low cardiac output results in end-organ dysfunction despite maximal medical therapy. The mainstay for support in children has been extracorporeal membrane oxygenation,^{36–38} which can sustain up to

TABLE 16-5

COMPARISON OF KEY OUTCOMES BETWEEN ABO-INCOMPATIBLE (ABO-I) AND ABO-COMPATIBLE (ABO-C) INFANTS AFTER CARDIAC TRANSPLANTATION

	ABO-I (N = 35)	ABO-C (N = 45)

Actuarial survival—7 yr	75%	74%
EBV disease or PTLTD	4 (11%)	5 (11%)
Graft vasculopathy	4 (11%)	5 (11%)
Mild	2	1
Severe	2	4
Wait-time (median)	25 days	26 days

Figure 16-16 Percentage of patients with implantation of a ventricular assist device (VAD) as a bridge to cardiac transplantation. (From Blume ED, Naftel DC, Bastardi HJ, et al, for the PHTS Investigators: Outcomes of children bridged to heart transplant with ventricular assist devices: A multi-institutional study. *Circulation* 2006;113:2313–2319.)

three-fifths of children to transplantation.^{39,40} In the experience at Toronto, the mean duration of mechanical support was 6 days, and almost four-fifths of patients survived to be discharged from hospital.⁴¹ Higher levels of creatinine before and during extracorporeal oxygenation, fungal infection, and high exposure to blood products, were factors for poor outcome. Patients supported using extracorporeal membrane oxygenation may have successful outcomes despite circumstances that previously may have been considered relative contraindications, such as cardiac arrest, or systemic bacterial infections. The approach should still be viewed, nonetheless, as a short-term bridge to cardiac transplantation because of the time-related risks for complications, such as infection, bleeding, and impairment of end organs. Consequently, devices capable of providing assistance over a longer term are now replacing extracorporeal membrane oxygenation.

Ventricular assist devices, primarily developed for adults, have been used in adolescents and larger children,^{35,42} and there is increasing experience with smaller devices⁴³ specifically designed for infants and children. As opposed to those receiving extracorporeal membrane oxygenation, patients supported with a ventricular assist device can usually be mobile and undergo physical and nutritional rehabilitation while awaiting transplantation. In a recent multi-centric review of outcomes, the median duration of support by ventricular assist device in children was 70 days,³⁵ with successful bridging in from two-thirds to four-fifths of patients.^{35,42,43} As expected, results have improved with increasing experience (Fig. 16-17),³⁵ but serious morbidity, including stroke, bleeding, and malfunction of the devices remain common, occurring in one-third of cases. Survival is lowest in those of younger age, and in those with congenitally malformed hearts (Fig. 16-18).³⁵ The current devices require extracorporeal pumps and pumping consoles, making them rather cumbersome. There are several fully implantable devices in development with the aim of long-term support to bridge children to transplantation and/or recovery.⁴⁴

Listing for Transplantation During Fetal Life

The improved accuracy of fetal echocardiography, and a better understanding of the natural history of cardiac disease

*Censored at transplant.

Figure 16-18 Survival to transplantation of patients after implantation of a ventricular assist device (VAD) stratified for (A) age at implantation and (B) congenital heart disease. Probability value is the unadjusted value. (From Blume ED, Naftel DC, Bastardi HJ, et al, for the PHTS Investigators: Outcomes of children bridged to heart transplant with ventricular assist devices: A multi-institutional study. *Circulation* 2006;113:2313–2319.)

diagnosed early in gestation, has allowed the possibility of listing for transplantation during pregnancy. Fetuses are listed, and delivered electively once a donor heart becomes available. The potential advantages of fetal listing include an

Figure 16-17 Competing outcomes analysis of cumulative proportion of patients with a ventricular assist device (VAD) who died or have received or are awaiting transplants. A, Early era (1993 to 1999; N = 49). B, Outcomes of the recent era (2000 to 2003; N = 50). The dotted line shows the percent of patients with each mutually exclusive end point at 6 months after implantation of the device. (From Blume ED, Naftel DC, Bastardi HJ, et al, for the PHTS Investigators: Outcomes of children bridged to heart transplant with ventricular assist devices: A multi-institutional study. *Circulation* 2006;113:2313–2319.)

extended time to wait for a donor organ, a favourable stage of immunological maturation, and avoidance of prolonged intensive care support with all its potential complications and morbidities. Potential disadvantages include high pulmonary resistance, with potential right heart failure in the transplanted heart, uncertainty of additional extracardiac lesions and/or undiagnosed chromosomal abnormalities, and a potential risk to the mother of an expedient delivery. A cohort of 26 fetuses listed for transplantation in Toronto has been reported.⁴⁵ Diagnoses considered for antenatal listing included hypoplastic left heart syndrome, other combinations producing a functionally univentricular arrangement with risk factors for traditional surgical palliation such as severe atrioventricular valvar regurgitation or decreased ventricular function, unresectable cardiac tumours, isomerism of the right atrial appendages, and intractable arrhythmias. The prenatal assessment included a detailed fetal echocardiogram for diagnosis, a complete anatomical antenatal ultrasonic investigation for other anomalies, amniocentesis for chromosomal analysis, and testing of maternal blood for viral exposure and other infectious diseases. Listing was usually at or beyond 35 weeks of gestation, when the fetus was deemed to have reached an age of pulmonary maturity, and an estimated fetal weight of greater than 2.5 kg.

MANAGEMENT OF THE DONOR AND RECIPIENT

Considerations Relative to the Donor

The mechanism of death, resuscitation, and the type of support required have a significant bearing on the suitability of an organ for transplantation. There is accumulating knowledge on the effect of brain death on cardiac function and the best methods to support the circulation to preserve cardiac function for subsequent donation. The response to acute traumatic brain death can be a profound decrease in ventricular function, with the myocardium of the right ventricle more affected than that of the left.⁴⁶ There is potential for functional recovery and seemingly borderline organs can become acceptable for transplantation with appropriate support.^{47–49} Therapy should be directed towards restoration of intravascular volume, and appropriate support of the myocardium and vascular system to ensure optimal cardiac output. Detailed discussion about the optimal management of the organ donor is published elsewhere,⁵⁰ but repeated echocardiography is essential to reassess suitability for donation.⁵¹ Even so, studies in animals and humans provide evidence for a continued susceptibility to dysfunction in the acute post-operative period, despite apparent functional recovery.^{46,52}

Much emphasis has been placed on the development of better cardioplegia and preservation solutions, and optimising temperature during transport after harvest of the donor heart. This is because an ischaemic time of more than 4 hours has been shown in multi-institutional studies to be a risk factor for poorer short- and long-term survival in adult recipients.⁵³ Interestingly, ischaemic times of more than 8 hours have been reported in children, without adversely affecting short- or long-term outcomes.^{54,55}

Although rarely a consideration in adults, in children the donor heart must be appropriately matched in size to the recipient. Widely disparate ratios of weight between

Figure 16-19 Ratio of the weight of the donor to the recipient as a risk factor for 1-year mortality. (From the registry of the International Society of Heart and Lung Transplantation. *J Heart Lung Transplant* 2007;26:796–807.)

donor and recipient, nonetheless, have been reported, with no adverse effect on outcome.^{56,57} In another study, oversizing by greater than 2.5 times was associated with pulmonary collapse and delayed sternal closure.⁵⁸ A recent analysis of the database of the International Society for Heart Lung Transplantation database has shown a ratio of less than 0.5, or more than 2.5, to be associated with an increased risk for mortality within the first year (Fig. 16-19).²

Age of the donor over 40 years has also been shown to be a significant risk factor for mortality when the heart is transplanted to an adolescent,⁵⁹ with similar results produced from analysis of the registry of the International Society for Heart Lung Transplantation registry.⁶⁰ As a result, within the protocols of both the United Network of Organ Sharing and the Canadian organ allocation, hearts from adolescent donors are allocated preferentially to adolescent recipients.^{15,61}

Surgical Techniques

The basic techniques for implantation of a cardiac allograft have not changed significantly since their original description.⁶² In children, the size of the patient, the location of the heart, atrial arrangement, systemic venous anatomy, and pulmonary venous anatomy must all be taken into consideration when determining the surgical approach. In some complex forms of congenital cardiac disease, there may be a need to harvest portions of the right and left pulmonary arteries, aorta, inferior caval vein, or the brachiocephalic vein to facilitate the anastomoses within the recipient. These details should be planned during assessment prior to transplantation. The surgical challenges pertaining to transplantation for patients with complexly malformed hearts have recently been reviewed.⁶³

Several retrospective studies have analysed outcomes related to the type of surgical approach. The bicaval approach has been reported to be associated with fewer tachyarrhythmias, slightly better haemodynamics, less tricuspid regurgitation, lower incidence of pacemaker support, and better exercise tolerance.^{64,65} The biatrial technique has been associated with disturbances of conduction requiring placement of pacemakers in up to one-sixth,⁶⁶ a higher risk of thromboembolism, poor atrial synchrony, and more atrioventricular valvar regurgitation due to distortion

Figure 16-20 Summary of maintenance immunosuppression in children receiving transplanted hearts. MMF, mycophenolate mofetil. (From the registry of the International Society of Heart and Lung Transplantation. *J Heart Lung Transplant* 2007;26:796–807.)

NOTE: Different patients are analyzed in year 1 and year 5

of atrial anatomy.⁶⁷ Other studies have shown no differences,⁶⁸ or only differences in the incidence of atrial tachyarrhythmias.⁶⁹ The only randomised trial demonstrated that the bicaval technique resulted in better haemodynamics and survival.⁷⁰

Management of the Recipient

There are several important postoperative issues that must be anticipated, and appropriately managed, in the recipient. The acutely denervated heart is frequently in slow sinus or junctional rhythm. Ventricular dysfunction as a result of ischaemia-reperfusion injury, compounded by brain death of the donor, can lead to acute decompensation of the transplanted heart, right ventricular failure being a specific concern. The latter is made more likely by elevated pulmonary vascular resistance, which commonly persists for days or weeks after transplantation. In general, strategies of post-operative management should be aimed at maintaining coronary arterial perfusion and systemic blood pressure by inotropic support, pulmonary vasodilators, chronotropy with either pacing or isoproterenol; optimising preload to the ischaemic and dilated right ventricle by limiting the circulating volume and central venous pressure, especially if there is systemic hypotension and/or low cardiac output previously unresponsive to fluid boluses; reducing the right ventricular afterload and pulmonary vascular resistance; ensuring an atrioventricular synchronous rhythm; optimizing ventilatory management to avoid hypercapnia and acidaemia by optimising peak early expiratory pressures and seeking early extubation; and providing early mechanical assistance to facilitate recovery of the transplanted hearts using extracorporeal membrane oxygenation, a ventricular assist device, or an intra-aortic balloon pump.

Specific Post-operative Complications

Stenosis can develop at the sites of the systemic venous anastomoses, the pulmonary arterial anastomoses, or the anastomosis of the reconstructed aorta. These may be amenable to interventional treatment, usually requiring implantation

of stents. Less commonly, the size of the left atrial anastomosis may be a problem. If it is haemodynamically significant, and not recognised in the operating room at the time of the post-operative transoesophageal echocardiogram, it will likely cause haemodynamic instability in the immediate period subsequent to transplantation, and may require early reoperation.

IMMUNOSUPPRESSION

The goal of immunosuppressive therapy is to prevent rejection, whilst minimizing morbidities related to chronic immune suppression. There are a large number of centre specific protocols for maintenance immunosuppression, with ongoing controversy regarding the optimal regime (Figs. 16-20 and 16-21). Indeed, there are a myriad of agents, dosages, protocols, and combinations that have been used for both induction and maintenance of immunosuppression, making definitive comparisons and recommendations difficult.² A detailed discussion of the various protocols is beyond the scope of this chapter.

MONITORING AND SURVEILLANCE AFTER TRANSPLANTATION

The hallmark of care subsequent to transplantation is meticulous attention to detail, with a high index of suspicion for transplant-related problems. Care of children after cardiac transplantation must account for physical growth and development, the stage of immunological development, intellectual, emotional and social maturation, educational activities, and other parameters of quality of life for children. Each one of these aspects can significantly affect morbidity and mortality after transplantation.

Rejection

Rejection is the process of destruction of genetically foreign material by the immune system of the host. It varies in severity and timing between individuals, and may wax and wane within an individual patient. Although acute rejection remains an important cause of mortality and morbidity

Figure 16-21 Summary of maintenance immunosuppression at 1 and 5 years after transplantation in children with transplanted hearts. AZA, azathioprine; MMF, mycophenolate mofetil. (From the registry of the International Society of Heart and Lung Transplantation. *J Heart Lung Transplant* 2007;26:796–807.)

after transplantation (see Table 16-3), its incidence has decreased as a result of improvements in perioperative immunosuppression. There are few identifiable risk factors for rejection prior to transplantation, other than sensitisation to HLA antigens. Pre-formed donor-specific anti-HLA antibodies can lead to humoral rejection within the first few hours after transplantation. Cellular rejection usually starts during the first few weeks, and is present to some degree in most patients. Rejection is most commonly mediated by T cells, though humoral rejection mediated by B-cell activation is increasing due to the larger number of patients sensitised to HLA antigens. There is increasing evidence for the role of both acute cellular rejection and antibody-mediated rejection on survival of the transplanted organ (Fig. 16-22)² and the development of vasculopathy.^{71,72}

The gold standard for diagnosis of rejection remains the endomyocardial biopsy. Biopsies are graded according to the revised criteria of the International Society for Heart Lung Transplantation.⁷³ Grade 0 R indicates no rejection, and is unchanged from the criteria of 1990. Grade 1 R now represents mild rejection, and includes grades 1A, 1B, and 2 from 1990. Grade 2 R indicates moderate rejection, and is the same as grade 3A from the earlier system. Grade 3 R represents severe rejection, and incorporates grades 3B and 4 from the previous categorisation. There is a trend towards

reducing the number of biopsies performed late after transplantation, with some centres discontinuing routine biopsies for surveillance of patients considered to be at low risk.^{74,75} There have been many efforts to identify and validate non-invasive tests for diagnosing rejection, including echocardiography, intramyocardial electrography, and profiling of gene expression. As yet, no non-invasive test has been developed to consistently and accurately diagnose and/or predict rejection.⁷⁶

The incidence of acute rejection peaks in the first month after transplantation, and then tapers off by 3 months (Fig. 16-23).⁷⁶ The early peak is delayed until the second month by the use of induction immunosuppression, but acute rejection still occurs. By 6 months after transplantation, three-fifths of patients have had at least one episode of acute cellular rejection.² The majority of recipients will have at least one further episode of rejection in the first year, but they are usually asymptomatic, and identified only by biopsy. These episodes are easily treated, and do not result in significant morbidity or mortality.

Of patients alive at 1 year, one-quarter will experience another episode of rejection within 3 years.²³ Mortality

Figure 16-22 Kaplan-Meier survival in children with transplanted hearts based on the presence of rejection within the first year after transplantation. (From the registry of the International Society of Heart and Lung Transplantation. *J Heart Lung Transplant* 2007;26:796–807.)

Figure 16-23 Freedom from first acute episode of rejection shown as a hazard function curve. (From Dodd DA, Cabo J, Dipchand AI: Acute rejection: Natural history, risk factors, surveillance, and treatment. In Canter CE, Kirklin JK: *Pediatric Heart Transplantation*. ISHLT Monograph Series, vol. 2. Elsevier, 2007, Chap. 9. Fig. 3, p. 143.)

among patients suffering late rejection is significantly higher than in those without such rejection.^{77–79} Episodes of late rejection are also more often associated with haemodynamic compromise requiring inotropic support, and represent antibody-mediated rejection. Rejection with haemodynamic compromise is associated with a higher incidence of failure of the graft and mortality, with only half of patients alive at 1 year after such an episode.^{23,79} Rejection often recurs, with only one-third of patients suffering one episode remaining free of subsequent episodes at 5 years following the event.⁷⁹

Risk factors for rejection, late rejection, rejection with haemodynamic compromise, and recurrent rejection include older recipient age, black or Hispanic race, more frequent early rejection, more than one episode in the first year after transplantation, and shorter time since a previous episode.^{23,77,80} More recently, interest has been focused on genetic polymorphisms affecting production of tumour necrosis factor- α and interleukin-10 and risk of rejection.⁸¹

Treatment of rejection depends on many factors, including the type, grade, time after transplantation, clinical and haemodynamic effect, and baseline immunosuppression. There is general agreement that mild rejection does not require specific intervention. Moderate rejection usually requires some degree of intensification of immunosuppression, which generally includes an oral or intravenous bolus of corticosteroid, and an increase in regular therapies. Any rejection with haemodynamic compromise requires haemodynamic support commensurate with the clinical presentation, and aggressive intensification of immunosuppression.

Allograft Vasculopathy

Risk Factors and Diagnosis

Allograft vasculopathy is a diffuse, chronic vascular injury to the graft. Ultimately, ischaemia results from circumferential thickening of the vascular intima with stenosis or occlusion (Fig. 16-24). Classical clinical signs associated with coronary arterial disease are rare in recipients of transplanted hearts. Since the transplanted heart is denervated, they may not experience characteristic chest pain, even in the face of significant myocardial ischaemia. Consequently, the first clinical manifestations may be symptoms of advanced disease, including congestive cardiac failure, syncope, ventricular arrhythmias, and death. Transplant vasculopathy is a leading cause of death beyond 3 years after transplantation (see Table 16-4).

Figure 16-24 Graft vasculopathy. A, Coronary angiography (single plane) demonstrating a smooth calibre regular lumen (arrows). B and C, Intravascular ultrasound of the same vessel at the sites indicated by the black arrows. Despite the normal appearing angiogram, note the difference in intimal thickening reflecting the presence of moderate graft vasculopathy as seen by ultrasound.

The pathogenesis of the vasculopathy is multi-factorial, but includes both immune and non-immune components. Commonly, there is donor-specific cell-mediated alloreactivity to vascular endothelium,⁸² which appears to be promoted by a number of cytokines and growth factors.⁸³ There is probably some relationship between number of acute cellular rejection episodes and the risk of vasculopathy (Table 16-6).^{2,84,85} Non-immune associations include infections with cytomegalovirus,^{86–88} hypercholesterolemia,⁸⁹ smoking,^{84,85} hypertension,⁸⁵ elevated homocysteine,^{90,91} and cumulative doses of prednisone.⁹²

The risk factors for vasculopathy in children are outlined in Table 16-7.⁹³ After the first year, allograft vasculopathy is the commonest cause of morbidity and mortality.² Figure 16-25 illustrates freedom from this complication for the first 9 years after transplantation, with the same data stratified by age shown in Figure 16-26. This is highly dependent on the aggressiveness of screening. Coronary angiography remains the gold standard, but it tends to underestimate the vasculopathy compared with

TABLE 16-6

RELATIONSHIP BETWEEN REJECTION AND ALLOGRAFT VASCULOPATHY (AV) IN CHILDREN WITH A TRANSPLANTED HEART

Rejection during 1st Year	REPORTED AV BETWEEN FIRST AND THIRD YEARS POST-TRANSPLANT			REPORTED AV BETWEEN THIRD AND FIFTH YEARS POST-TRANSPLANT

TABLE 16-7

COMBINED DONOR/RECIPIENT RISK FACTORS FOR ALLOGRAFT VASCULOPATHY IN CHILDREN

Risk Factor	Single-centre Study	Multi-centre Study or Registry	Diagnostic Tools*
Older recipient age	Yes	Yes	Angio, IVUS
Older donor age	Yes	Yes	Angio
Acute rejection in first year after heart transplant	Yes	Yes	Angio
High acute rejection frequency rate	Yes		Angio, IVUS
Lower immunosuppression (double vs. triple)	Yes		Angio
Late (>1 yr) acute rejection with hemodynamic compromise	Yes		Angio, IVUS
Earlier year of heart transplant	Yes		Angio
Late (>1 yr) acute rejection	Yes		Angio, IVUS
Cytomegalovirus infection	Yes		IVUS
No pravastatin therapy	Yes		Angio
Viral genome by polymerase chain reaction	Yes		Angio or autopsy

Angio, angiography; IVUS, intravascular ultrasound.

pathological examination or intravascular ultrasound (see Fig. 16-24).^{94,95} In addition, angiography provides minimal information on the impact of allograft vasculopathy on cardiac function. Once allograft vasculopathy is evident angiographically, short-term mortality is high (Fig. 16-27).^{94,95} Supportive evidence for the presence of ischaemia may be obtained by exercise testing and nuclear medicine scintigraphy, but the application of these testing modalities is limited to older, cooperative patients and abnormalities may only be apparent at a relatively advanced stage of disease.⁹⁶

The use of dobutamine stress echocardiography has been advocated in adult recipients for routine surveillance for allograft vasculopathy,⁹⁷ in some centres even replacing routine angiography. Several studies in adults have shown a relationship between an abnormal test and events related to allograft vasculopathy.^{94,95,97} Preliminary studies in children have supported the feasibility and safety of such testing, in addition to providing preliminary evidence for a role in identifying children with allograft vasculopathy.^{98–101}

Because of the limitations of angiography, intravascular ultrasound has been proposed as a better means of

Figure 16-27 Kaplan-Meier survival following diagnosis of cardiac allograft vasculopathy (CAV) in children with transplanted hearts stratified by age group. (From the registry of the International Society of Heart and Lung Transplantation. J Heart Lung Transplant 2007;26:796–807.)

identification and study of progression of epicardial coronary arterial disease (see Fig. 16-24). The early enthusiasm has been tempered by technical issues, cost, and lack of meaningful end-points for management and/or prognosis. Its use is presently limited to older children due to the size of the available catheters.

Management

Lipid-lowering therapy, using statins, has been shown to play a role in the prevention of allograft vasculopathy. In adults, pravastatin has been shown to reduce the incidence of acute rejections associated with haemodynamic compromise, improve survival at 1 year, and reduce the development of vasculopathy.¹⁰² This was independent of the level of cholesterol, suggesting the effect of statins extends beyond manipulation of lipids. Similar findings have been reported with simvastatin.¹⁰³ There is limited data in children, but two studies have shown a lower incidence of vasculopathy during treatment with simvastatin¹⁰⁴ or atorvastatin.¹⁰⁵ There is accumulating data in adults on the potential role of different immunosuppressant agents on the development of intimal thickening, including mycophenolate mofetil, sirolimus, and everolimus, but these are short-term studies, and do not include children.⁹³

Treatment of established allograft vasculopathy is challenging, especially in children. In adults, percutaneous transluminal angioplasty and/or stenting of discrete lesions has been successfully performed.¹ The majority of patients are not amenable to these techniques due to the diffuse nature of the disease. Similarly, coronary arterial bypass grafting has also been successfully performed, but has a very limited role.¹ There are only two reports of interventions in a small number of children, making definitive recommendations impossible.^{106,107} Ultimately, patients with moderate-to-severe vasculopathy and evidence of graft dysfunction may be candidates for retransplantation.

Retransplantation

The assessment of need for retransplantation is an important element of management of children undergoing their first transplantation. There has been an increasing number of retransplantations in North America over the last few years (Fig. 16-28; see also Figs. 16-4 to 16-6), with most performed more than 5 years following the initial procedure (Fig. 16-29). Review of the database of the United Network for Organ Sharing for the period between 1987 and 2004 revealed 19 children who underwent retransplantation (Table 16-8).¹⁰⁸

Overall survival following retransplantation approaches that of primary transplantation, when retransplantation occurs later than 1 year after primary transplantation (Fig. 16-30). Retransplantation for early failure or acute rejection, the usual causes of death in the first year, carries a high mortality. For patients transplanted within 1 year of their first transplantation, the 1 year actuarial survival is 60%, compared to almost 90% for those retransplanted later than 3 years.

Exercise and Aerobic Capacity

Exercise restriction is not usually necessary after transplantation. Indeed, a benefit was found when comparing a regimented monitored programme for cardiac rehabilitation and exercise in a large randomised study of adults.⁹⁷

INDICATIONS FOR RETRANSPLANTATION

	N = 219 (%)
Allograft vasculopathy	111 (51%)
Nonspecific graft failure	34 (16%)
Acute rejection	19 (9%)
Chronic rejection	16 (7%)
Primary failure	10 (5%)
Hyperacute rejection	7 (3%)
Other	22 (10%)

From Mahle WT, Vincent RN, Kanter KR: Cardiac retransplantation in childhood: Analysis of data from the United Network for Organ Sharing. *J Thorac Cardiovasc Surg* 2005;130:542–546.

Structured cardiac rehabilitation has also been useful for adolescents. For younger patients, and those teenagers who cannot participate in such a programme, we recommend 30 minutes of aerobic exercise three to four times a week. Children can generally return to routine exercise once their incisions have healed, this generally being after 6 to 8 weeks.

Figure 16-30 Kaplan-Meier survival for retransplantation in children with transplanted hearts by intertransplant interval. (From the registry of the International Society of Heart and Lung Transplantation. *J Heart Lung Transplant* 2007;26:796–807.)

Following transplantation, physiological responses to exercise may be impaired. This is related to several factors, including age at transplantation,¹⁰⁹ deconditioning prior to transplantation, growth of the allograft,^{110,111} degree of reinnervation,^{112–115} chronotropic incompetence,^{116–118} comorbidities such as renal dysfunction, respiratory abnormalities, and so on, and the effects of medication such as corticosteroids and cyclosporine on skeletal muscular function. Studies examining exercise performance in children have demonstrated a blunted response of heart rate to graded exercise, and decreased maximal consumption of oxygen,^{117,119,120} albeit that one group of children has been identified with heart rate responses faster and greater.¹¹⁸ Despite near normalisation of rate responses in this group, maximal consumption of oxygen remained submaximal. There are a few studies demonstrating a more

normal rate response and a low normal maximal consumption of oxygen.^{109,121}

The largest and most recent series of serial exercise tests in children demonstrated better exercise capacity associated with younger age at transplantation, especially for infants, a positive relationship between peak heart rate and time subsequent to transplantation, good exercise capacity with a mean maximum consumption of oxygen of 30 mL/kg/min at a mean of 5.5 years after transplantation, which is but mildly reduced compared to the normal population, and a possible association with changes on serial studies and the presence of allograft vasculopathy.⁹⁶

Infections

Analysis of the data collected by the Pediatric Heart Transplant Study showed reported infections to occur in two-fifths of patients during a period of 2 years.¹²² Such infections are an important cause of morbidity and mortality after transplantation. A report from the International Society of Heart Lung Transplantation identified infection as the second commonest cause of death within the first year after transplantation (see [Table 16-4](#)).² Several factors determine the risk of infection ([Fig. 16-31](#)).¹²³ Certain infections may become reactivated following introduction of immunosuppression. Serological testing prior to transplantation helps identify the possibility, and routine surveillance can sometimes guide prophylactic or pre-emptive treatment. Not all infections are amenable to prophylactic treatment, and under those circumstances reactivation of disease may also require specific treatment. Of special mention is the impact of Epstein-Barr virus in seronegative recipients. Prophylaxis is controversial, and surveillance should include regular testing for active viral replication by polymerase chain reaction techniques. Conversion to seropositivity for Epstein-Barr virus requires consideration of anti-viral therapy, especially in the first 6 months after transplantation. Patients with a chronic viral load should be regularly investigated for the development of lymphoproliferative disorder.

Figure 16-31 Factors that determine the risk of infection in children with transplanted hearts. (From Renoult E, Buteau C, Lamarre V, et al: Infectious risk in pediatric organ transplant recipients: Is it increased with the new immunosuppressive agents? *Pediatr Transplant* 2005;9:470–479.)

Most children undergoing transplantation have not finished their routine schedule of immunisations. Titres should be checked prior to transplantation. Efforts should be made to immunise with as many vaccinations as is feasible and developmentally appropriate prior to transplantation. This is particularly important with vaccines that incorporate live viruses. Vaccination schedules should be resumed approximately 6 months after transplantation. Given the suppression of the immune system and the variable responses to foreign antigen, antibody titres should be checked after vaccination in order to ensure an appropriate response. In general, live viral vaccines are avoided.

Renal Function

There is increasing awareness of the adverse effects of renal dysfunction on outcomes after transplantation. There are many causes for the gradual decline that is common in these patients. In addition to the preoperative compromise that results from low cardiac output, chronic diuretic therapy, or mechanical support, there is often an acute perioperative decline reflecting the ischaemia/reperfusion injury following cardiopulmonary bypass and the use of multiple nephrotoxic drugs. In the long term, the cumulative use of calcineurin inhibitors leads to structural changes at all levels of the kidney. This is characterised by glomerulosclerosis, tubular atrophy, interstitial fibrosis, and afferent arteriopathy.^{124–127} In a comparison of inhibitors of calcineurin inhibitors, no difference was observed in the decline of calculated clearance of creatinine when tacrolimus was compared with cyclosporine.¹²⁸

The reported incidence of renal insufficiency varies depending on the definition used and the method used for assessment.¹²⁶ In most cross sectional reviews, no more than 1% or 2% of patients have progressed to end-stage renal failure requiring dialysis and/or renal transplantation.¹²⁸ Another study showed the percentage of patients with a normal rate of glomerular filtration to be 78% at the time of transplantation, reducing to 45%, 29%, and 14% at 1, 2, and 5 years after transplantation.¹²⁷ Analysis of the database of the International Society of Heart Lung Transplantation shows the incidence of renal dysfunction to be 6.0% at 1 year, and 9.3% at 5 years (Tables 16-9 and 16-10).²

Close follow-up of renal function is clearly required. Clearance of creatinine may be estimated from the levels in the serum and the height of the patient, albeit that such calculated values consistently overestimate the measured rate of glomerular filtration.^{126,128} Strategies to improve renal function should be directed towards reducing or eliminating exposure to nephrotoxic agents, including the inhibitors of calcineurin. Partial improvement in renal function may occur after the dose of such inhibitors is reduced, even after years of use. This reversible component of renal dysfunction is secondary to persistent afferent arteriolar constriction and decreased renal blood flow. Recently, the use of immunosuppression using sirolimus as a calcineurin sparing agent has shown some benefit in patients with moderate renal dysfunction.¹²⁹

Lymphoproliferative Disorders

Malignancies are another important cause of morbidity and mortality after transplantation. They can occur as new events, be a reactivation of previous cancer, or result from

TABLE 16-9

PREVALENCE OF MORBIDITIES AFTER TRANSPLANTATION IN SURVIVORS AT 1 YEAR AFTER TRANSPLANTATION

Outcome	Within 1 Year	Total Number with Known Response

Data from the registry of the International Society of Heart and Lung Transplantation. J Heart Lung Transplant 2007;26:796–807.

chronic viral infections, with the latter being most important in children. The cumulative prevalence in survivors is 2% at 1 year, 5% at 5 years, and 7% at 10 years (Fig. 16-32 and Table 16-11).² The reported overall incidence of such disorders as analysed in the database of the Pediatric Heart Transplant Society was 5%.¹³⁰ Survival in those with the disorder was 95% at 1 month, 75% at 1 year, and 67% at 5 years.¹³⁰ There may also be a temporal relationship to incidence, Ross et al reporting a 23% incidence in survivors more than 10 years after transplantation.¹³¹

The lymphoproliferative disorders include all clinical syndromes associated with lymphoproliferation after transplantation. The spectrum ranges from a mononucleosis-like illness to life-threatening malignancies with clonal chromosomal abnormalities. Epstein-Barr virus plays a major role in their development, with the highest risk for development being a primary infection with the virus. As noted above, given their naivety to Epstein-Barr virus, primary infection, and consequently occurrence of the disorders, is

more common in children. The risk is also clearly related to the viral load.¹³²

There are no controlled clinical trials comparing interventions or therapies for these disorders. Treatments include reduction in immunosuppression, anti-viral medication, immunoglobulin therapy, monoclonal antibodies such as rituximab,^{133,134} chemotherapy, tumour debulking, radiation therapy, and rarely, bone marrow transplantation.

Growth

Retarded growth is frequent in children after cardiac transplantation. In the population followed by the Pediatric Heart Transplant Society, the rate of growth fell between the time of listing and the time of transplantation. Catch-up linear growth occurred during the first year, but patients remained shorter than their age-matched peers at 6 years after transplantation. Children transplanted for reasons other than a congenital cardiac disease maintained steady linear growth after transplantation, but also failed to achieve normal height. Patients with a diagnosis of hypoplastic left

heart syndrome, or those at a younger age at transplantation, showed less catch-up growth.¹³⁵

Development

Formal assessment of infant development has been carried out in a large cohort of babies transplanted by the group in Loma Linda.^{136–139} Overall, their mean developmental scores, for both mental and psychomotor indexes, fell within normal limits, though they tended to be at the lower end of normal. Reports beyond infancy demonstrate a range of variation in a spectrum of developmental parameters compared to a normal population, with overall cognitive scores at the lower limit of normal.^{13,140–143} Focused studies of patients born with hypoplastic left heart syndrome all demonstrate lower scores on the scales for infant development and intelligence compared with the general population, but similar to patients undergoing the Norwood sequence of palliative procedures.^{144,145}

Quality of Life, Psychosocial Issues, and Non-adherence

While most children and families report a good quality of life,¹⁴⁶ psychosocial and adverse functioning has been reported.^{141,142,147–151} A longitudinal study of children after transplantation of either the heart or the heart and lungs showed academic cognitive functioning to be in the normal range, and not to change as a function of time from transplantation.¹⁴¹ Performance at school, nonetheless, was significantly poorer than that of healthy children, and the prevalence of behavioural problems rose significantly. Similar results were reported in another longitudinal study, which followed children for more than 10 years, with psychological functioning outside the normal range in one-quarter of patients.¹⁴⁹ In this latter cohort, there was significant improvement in emotional functioning compared to findings prior to transplantation, and the severity of the medical disability before transplantation was not correlated to subsequent psychologic function.¹⁴⁸ These results concur with other studies in which the severity of illness is less important to adaptation than other factors. Illness-related stress, and symptoms of post-traumatic stress, are significant problems affecting parents of children undergoing transplantation, with nearly two-fifths of one cohort of parents declaring moderately severe to severe symptoms of post-traumatic stress.¹⁵¹ Pre- and post-operative psychological assessment, and support of the patient and his or her family, is clearly an important role of any centre involved in cardiac transplantation.

Non-adherence to complicated and life-sustaining therapy is less well studied. The complex psychological issues described above, combined with normal adolescent development after cardiac transplantation, render a large population of recipients at risk of rebellious or risk-taking non-adherence.^{152–153} Non-adherence has been linked to late rejection,¹⁵⁴ and to high rates of death in adolescents.¹⁵⁵ It has been suggested that high variability in trough levels of medications, with both high and low levels presumably reflecting variable adherence, was a sensitive marker for children at greater risk for recurrent rejection and hospitalisation after transplantation.¹⁵⁶ A coordinated effort between paediatricians, the transplant team, the

patient, and family must be in place to help identify those recipients at risk, particularly at the time of transition from paediatric to adult-based care.

Other Complications

Hypertension has been noted in almost half of recipients at 1 year, with this proportion increasing to two-thirds at 5 years, and almost three-quarters at 10 years after transplantation² (Table 16-12). Abnormalities of lipids and lipoproteins are more prevalent in children after cardiac transplantation compared to their age-matched controls.^{80,157} These abnormalities are related to immunosuppressant agents such as cyclosporine, corticosteroids, and sirolimus; obesity, which is often steroid-induced; and diabetes, the latter also associated with steroids and tacrolimus. Small single-centre studies have demonstrated the safety and efficacy of treatment of children with statins after transplantation,^{105,158} and some have suggested a lower incidence of allograft vasculopathy in patients treated in this fashion.¹⁰⁸ Other complications include hypomagnesaemia and cosmetic side effects, such as hirsutism, gingival hyperplasia, acne, and loss of hair.

TRANSPLANTATION OF THE HEART AND LUNGS

Transplantation of the heart together with the lungs has limited application in children, with this procedure peaking in the late 1980s, with 40 procedures, and reaching a nadir in 2002, with 9 procedures, according to the registry of the International Society of Heart and Lung Transplantation.¹⁵⁷ It is indicated for severe pulmonary vascular disease or pulmonary vascular issues when the cardiac lesions are not amenable to conventional surgery. It has also been used in end-stage lung disease with concurrent left ventricular dysfunction felt to be irreversible in nature. Most right ventricular failure in association with pulmonary vascular disease is amenable to bilateral transplantation of the lungs. Post-operative transplant-related morbidities are similar to those for isolated transplantation of the heart and the lungs, with the issues relating to transplantation of the lungs predominating, and generally guiding the clinical course and plans for treatment. Risk factors for mortality include ventilation at transplant, infection,

and obliterative bronchiolitis. Long-term outcomes are well below those for transplantation of the heart, and have shown no improvement over the last decade, with a 5-year survival of less than 50%.

FUTURE DIRECTIONS

Overall, the survival for children undergoing transplantation of the heart has improved remarkably during the past 20 years, and the functional state of most patients remains good for many years following surgery. Despite this, there is a continuing risk of major late morbidity. Development of new immunosuppressant agents that decrease the morbidity for children following transplantation will be crucial to modify these late adverse outcomes. Mortality whilst waiting for transplantation remains unacceptably high. Improved management of cardiac failure, and improved technology more effectively to bridge these young patients to transplantation, will help reduce these deaths occurring during the period of waiting, but ultimately societal change will be required to widen the pool of available donors. The holy grail remains the induction of complete immune tolerance of the recipient to the implanted organ.

This article summarises the revised consensus for classification of cardiac allograft rejection. Recommendations are also made for the histological recognition and immunohistological investigation of acute antibody-mediated rejection.

Interventional Techniques

SACHIN KHAMBADKONE and PHILIPP BONHOEFFER

Interventional cardiac catheterisation describes procedures where cardiac catheters are used to modify, palliate, or treat congenital or acquired cardiac disease. Evolution of interventional techniques has been a natural progression from surgical procedures used to treat such lesions. The development of newer interventional techniques has largely been possible by pushing the boundaries of established interventional procedures in order to achieve results comparable with surgical techniques. Although the aim is to do something to alter the course of disease the basics of interventional catheterisation are drawn from experience with diagnostic cardiac catheterisation. Not all interventional catheterisation techniques are therapeutic. Some do no more than modify the course of the disease, or help delay future interventional or surgical procedures. The design and organisation of the catheterisation laboratory, personnel, use of equipment, catheters and techniques are a progression of the exercise of gathering of information related to diagnostic catheterisation and angiography. In sick neonates, infants, and children, however, any catheterisation is an intervention, involving higher risks than therapeutic elective procedures performed in stable patients.

HISTORICAL BACKGROUND

The evolution of interventional techniques has followed the basic principles of cardiac catheterisation outlined by Werner Forssman in 1929. The use of interventional catheterisation was first initiated by the use of balloon dilation in pulmonary and tricuspid valvoplasty,¹ and in dilation of atherosclerotic lesions.² It was Rashkind and his colleagues who widened the therapeutic implications of interventional catheterisation with the first intracardiac procedure in paediatrics and congenital cardiac disease when they introduced balloon atrial septostomy.^{2,3} The use of occlusive devices was first reported by Porstmann and his colleagues in 1967, when a patent arterial duct was occluded with the aid of an Ivalon plug.⁴ Attempts were then made to close left-to-right shunts with other devices, such as an atrial septal occluder for atrial septal defects,⁵ and the double umbrella device for the persistently patent arterial duct and atrial septal defects.⁶ The application of percutaneous transluminal balloon angioplasty by Gruntzig and Hoppf in 1974⁷ was a landmark that expanded the field of interventional cardiology to the situation where it became recognised as a subspecialty in its own right. The principles of percutaneous transluminal balloon angioplasty were first applied by Lock and his colleagues⁸⁻¹¹ in the field of congenital cardiology, when they addressed stenotic pulmonary arteries, the aorta, and systemic veins, both in animal experiments and

in humans. Kan and colleagues,¹² in 1982, then reported the first use of balloons introduced percutaneously for dilation of congenital valvar pulmonary stenosis. This approach has since become an accepted first intervention for treatment of stenosed pulmonary and aortic valves. The development of balloon-expandable stents has helped overcome problems of residual stenosis and restenosis in vessel walls.¹³ The development of newer materials, such as Nitinol, a nickel-titanium alloy, has revolutionised technology, and expanded its use in closure of left-to-right shunts.¹⁴⁻¹⁶ The use of this shape-memory alloy has simplified the delivery and retrieval of these devices by significantly reducing the size of the catheters used for delivery, thereby increasing their application in infants and smaller children. Various designs are now available, with different characteristics, allowing the operator to choose the most appropriate device for the morphology of the defects. Transcatheter insertion of valves is the most recent development in the field of interventional catheterisation.¹⁷ Percutaneous implantation of biological or pericardial tissue valves mounted on balloon-expandable or self-expanding stents are now clinically approved for use in treatment of stenotic and regurgitant lesions in both the left and right ventricular outflow tracts.¹⁸⁻²² Transcatheter techniques for repair of the mitral valve, based on surgical principles such as the creation of dual orifices and annuloplasty, are also being actively investigated in the clinical setting.^{23,24} The final frontier in interventional techniques could well be the transcatheter treatment of complex congenitally malformed hearts, replacing surgical interventions such as the Norwood procedure or completion of Fontan circulation.²⁵⁻²⁸

PRINCIPLES OF CATHETERISATION

The field of interventional catheterisation is rapidly expanding as newer techniques and devices appear on the market. Any description of a standard procedure is, therefore, unlikely to stand the test of time, and will soon be outdated. The basic tenets of interventional catheterisation, however, are likely to remain constant, and have already stood the test of time over the last few decades. The success of an interventional catheterisation procedure is dependent not only on the performance of the procedure, but also on good planning prior to the procedure, coupled with anticipation and preparation for unexpected events.

Pre-procedural Planning

Consent should ideally be obtained either during outpatient consultation, or in a dedicated pre-admission clinic that provides parents the opportunity to discuss relevant issues.

The consent should be obtained by a person suitably qualified, with sufficient knowledge to explain the procedural details and its risks or, ideally, by the senior cardiologist. It is unreasonable to expect to receive a blanket consent, covering all procedures, although detailed consent for specific anticipated events might be obtained. The patient and the family should have sufficient time and information to make a fully informed decision. As it is difficult to approach parents during catheterisation for consent to additional procedures, treatment of life-threatening complications, or events that may lead to significant deterioration in the health of the patient, must be performed as deemed necessary.²⁹

The planning of an interventional catheterisation procedure cannot be over-emphasised. Procedural planning aids in giving sufficient time to order necessary laboratory equipment and devices not stocked on a regular basis. Admission of the patient should include a meeting with the patient and family, explaining details and risks associated with the procedure, so that any doubts and fears specifically pertaining to the procedure are reclarified. All investigations should be reviewed on the day of the procedure. A repeated clinical examination of the patient helps determine the need for any additional investigations. Imaging should be reviewed to reconfirm the diagnosis, and the decision made for the procedure. Ideally, the symptoms, findings on clinical examination, and investigations should be reviewed by a team of doctors, including the primary cardiologist, the interventional cardiologist, the imaging cardiologist, the anaesthetist and, if applicable, the cardiac surgeon, in order to maximise the information leading to the procedure. An approach based on consensus also adds to the safety and efficacy of the decision-making process, as individuals with different areas of expertise contribute in a complementary manner, maximising the benefit to every patient. Use of additional cross sectional imaging, such as three-dimensional echocardiography, magnetic resonance imaging, or computerised tomography, can add significantly to the clinical information by providing details of complex cardiac anatomy that could suggest the need for a modified approach, or even contraindicate catheterisation. Decisions regarding access, via the femoral, jugular, or bilateral jugular approach, for example, choice of sheaths, catheters, wires, dosage of contrast agents, and projections to be used, can be made with reasonable certainty before starting the procedure. It is always helpful to discuss the whole strategy in a step-wise manner with the fellow in training, scrub nurse, cardiac physiologist, anaesthetist, radiographer, and all staff involved with the procedure. Steps that can be performed quickly and safely should be identified and delegated to assistants in the interest of time, particularly for long procedures.

Vascular Access

The conventional approach, namely to have both an arterial and a venous access, works in almost all situations where interventional catheterisation is performed. Femoral, internal jugular, subclavian, axillary and hepatic vascular approaches have all been used for various interventions. The possible need for reintervention should be borne in mind, thus avoiding unnecessary access. Repeated catheterisation, prolonged periods in intensive care, and multiple

operations for complex staged palliative procedures can make access difficult due to repeated use of the vessels. Ultrasonically guided access allows for visualisation of vessels, detects unusual arrangements, thrombosed veins and arteries, and also reduces the risk of inadvertent puncture. Stenosis or atresia with luminal continuity of systemic veins may have to be dealt with by crossing the site with a floppy-tipped guide-wire, and use of long sheaths, which go across the stenosis and provide access to the central circulation. On the arterial side, in small neonates or infants, vascular cut-down has been used to access the carotid or axillary arteries for interventions on the aortic valve or arch.^{30,31} In neonates and small infants, the availability of small catheters and sheaths, of 3 and 4 French sizes, have facilitated procedures, and reduced the risk of vascular injury.³²

Catheters and Guide-Wires

In infants and children, angled and curved tipped catheters are most commonly used in situations where catheters need to be manoeuvred through tight bends and small chambers and vessels. The operator needs to have sufficient knowledge of the differences in the types of catheter when performing cardiac and peripheral interventions in order to modify the approach to access difficult sites. Hydrophilic catheters, such as the Glide catheter, Medi-tech, or Boston Scientific products, track well over guide-wires into difficult sites. Balloon-tipped catheters, such as the Berman angiographic catheter, or the Arrow balloon wedge catheter, are useful for wedge injections, or to cross atrioventricular valves without entrapment in the intercordal spaces. Catheters of short length help make manipulation easy in small babies. Long catheters in older patients help to form loops in dilated proximal chambers, such as the right atrium, to provide stability, and allow tracking into distal vessels such as the pulmonary trunk.

Guide-wires are used to access vessels, stabilise catheters, and provide easy access for multiple crossings of stenotic lesions. A soft hydrophilic wire, such as the Terumo, with an angled tip, can be used to enter small tortuous vessels. A stiff exchange length wire, such as the 0.035-inch, 260-cm product from Cook (Bloomington, IN), is usually required to obtain multiple haemodynamic measurements, provide stability across a lesion, for multiple crossings after interventions, to perform angiography, and to mount balloon catheters, stents, or large sheaths.

Anti-coagulation

Heparin is used as an anti-coagulant during cardiac catheterisation to prevent thromboembolism during and after the procedure. Some operators monitor heparin effect by measuring the activated clotting time or the partial thromboplastin time, albeit that most use a standard dose based on the weight of the patient.³³

For short procedures, a single dose of 50 units per kilogram body weight is administered after vascular access is obtained. For long procedures, between 100 and 200 units per kilogram weight is administered and may be repeated either after 2 to 3 hours or by monitoring either the activated clotting or the partial thromboplastin times. Protamine may be used to reverse the effect of heparin should there be persistent bleeding from the site of access.

INTERVENTIONAL CATHETERISATION PROCEDURES

Balloon Dilation

Balloon dilation is performed to relieve stenosis of valves, vessel walls, surgically-created pathways, or intracardiac structures such as a fenestration in the atrial septum. There have been significant advances in the size, profile, design and materials used in balloon catheters, facilitating their use in various applications. Design of co-axial balloons has reduced the time required for inflation and deflation, with only transient haemodynamic compromise. The size of the balloon used for a particular procedure not only depends on the diameter of the lesion to be dilated, but also on the diameter of the contiguous and non-contiguous normal anatomical structures. The use of an over-sized balloon increases the chance of a successful dilation of the lesion, but also increases the risk of trauma to contiguous anatomical structures. Balloons have been used to treat valvar stenosis when fusion of the leaflets along their zones of apposition is responsible for reduction in the effective valvar orificial area. The principle of creating a controlled tear or split along the zone of apposition, thus improving excursion of the leaflets, provides a better effective orificial area, and relieves the stenosis. As the valve is abnormal, competence may be affected to various degrees after balloon dilation. Pulmonary, aortic, mitral, and tricuspid valves have all been treated by balloon valvoplasty for different diseases. The technique, however, is not useful in treating valves that are hypoplastic because of narrowing at the ventriculo-arterial junction. Dilation of arterial valves is performed commonly for congenital lesions, and dilation of atrioventricular valves is performed almost exclusively for acquired lesions. The technique used in performing balloon valvoplasty also forms the basis for angioplasty and implantation of stents. High-pressure balloons have been more recently used in dilating tight lesions, such as calcified conduits or pulmonary arterial stenosis.^{34,35} Cutting balloons have been used in substrates which do not respond to standard balloon angioplasty, such as severe pulmonary arterial stenosis or recurrent pulmonary venous stenosis, with encouraging results.³⁶ Balloon-in-balloon catheters, known as BIB, and produced by NuMed (Hopkinton, NY), have been very useful in implanting stents in the aorta and pulmonary arteries.³⁷ The inner balloon is an additional tool to help confirm the position before deployment of the stent. The use of two balloons inserted over a single guide-wire for valvoplasty was first introduced for dilation of the mitral valve.³⁸ It provides a large effective diameter of the combined balloons, and has been used in pulmonary valvoplasty in adults who have a large diameter of the pulmonary outflow tracts.³⁹ Stability of the balloon during inflation depends on choice of a balloon of correct length and diameter, appropriate selection of a stiff guide-wire, obtaining a good position for the guide-wire, and achieving a rapid sequence of inflation and deflation. Stability could be further aided by using techniques to reduce stroke volume, such as rapid ventricular pacing, mainly for lesions in the systemic circulation. In balloon valvoplasty, the size of the balloon is chosen based on the size of the valve measured. In pulmonary valvoplasty, the balloon size is usually one-fifth to one-quarter larger than the measured diameter of the valve at the basal hinge points of the leaflets. In aortic valvoplasty, the size is usually

nine-tenths of the diameter at the hinges of the leaflets. Size for dilating the coarcted aorta equals the diameter of the proximal transverse arch, or a size is chosen not greater than three times the size of the lesion, but less than the diameter of the descending aorta at its position close to the diaphragm. The length of the balloon should not be so short as to produce instability during inflation, and not too long to cause trauma to the proximal or distal structures. The size of the patient should be taken into consideration in choosing the correct balloon. Balloons are filled with contrast medium diluted 1 in 5 with saline, and should be de-aired thoroughly to reduce the risk of air embolism, should the balloon rupture. If the margins of the balloon, at its ends, are parallel, it suggests that inflation is at nominal pressure, and any further inflation can increase the risk of rupture. After successful dilation, haemodynamics and angiography should be repeated to evaluate results and assess complications. Further evaluation by echocardiography is imperative to decide long-term management.

Stent Angioplasty

Stents are capable of maintaining patency of vessels and prevent elastic recoil after balloon dilation. There have been major advances in stent technology, and their impact can be easily observed in congenital cardiology. Typically, stents are cut from stainless steel tubes with a laser, or made from platinum alloy wires welded together. Stents can be expanded on balloons, or be self-expanding when made of shape-memory alloy and covered by a sheath. Self-expanding stents are used in patients who have already achieved their potential for growth. Balloon-expandable stents can be redilated within limits, and may be used in children. The design of the cells may be open, avoiding jailing or covering of neighbouring arterial branches, or closed. The properties of materials considered favourable for use in congenital cardiology are those with a low profile, good strength and flexibility, and ability to withstand cyclic compressive stresses of the cardiovascular system. The diameter of the stent should also have the potential to reach maximal dimensions of the vessel wall as seen in the adult. In small infants, however, a coronary arterial stent may be used in extenuating circumstances of severe haemodynamic compromise, despite its limited final maximal diameter. Stents are implanted using balloons of appropriate size through long, large-bored, sheaths to reach the lesion. Stents may be pre-mounted on the balloons, or may need to be crimped on to the balloon manually or by using a crimping device. The length of the balloon should always be longer than the length of the stent. The diameter of the balloon determines the final diameter of the stent. Stability of the stent during deployment can be improved by using the balloon-in-balloon catheters, extra-stiff wires, long sheaths, and rapid right ventricular pacing to reduce stroke volume.⁴⁰ The luminal surface of the stent endothelialises in 8 to 10 weeks, and patients may need to take anti-platelet agents or, in some situations, anti-coagulants during this period to prevent in-stent restenosis.

Risks associated with stent angioplasty include dislodgement and embolisation, trauma to the vessel walls, fracture of the stent, and restenosis. Covered stents made by suturing expanded polytetrafluoroethylene to balloon-expandable or self-expanding stents have been used in situations where

the risk of vascular injury and aneurysm is considered to be high. The use of these covered stents in younger patients is limited by their size, and the calibre of the delivery systems currently available. Newer bioabsorbable stents are currently being investigated to reduce restenosis in coronary arterial lesions. If approved, these stents could prove useful in treating stenosis of small vessels in infants, albeit temporarily, thus allowing for normal growth.⁴¹

Closure of Septal Defects and Vascular Occlusion

The advent of shape-memory alloy has revolutionised transcatheter interventions for intra- and extracardiac shunts. Nitinol is the most common alloy used. Several devices for closing septal defects and vascular occlusion are currently available. The most commonly used occluder, produced by Amplatz at AGA Medical, has a central occluding part, with left- and right-sided discs. A Dacron polyester patch sewn into the device is responsible for thrombogenicity and complete occlusion. Sizing of a septal defect is performed by trans-oesophageal or intracardiac echocardiography, or by inflating a balloon during the procedure. Reported complications of such devices eroding through the atrial or aortic walls, and devices designed to occlude ventricular septal defects causing complete heart block, emphasise the importance of choosing a device of appropriate size. Various practices from over-sizing, to reduce the risk of embolisation, to appropriate sizing, to reduce the risk of trauma to contiguous structures, have been used.

INTRACARDIAC INTERVENTIONS

Valvar Heart Disease

Pulmonary Valve

Pulmonary Valvar Stenosis

As already discussed, the initial description of balloon dilation of pulmonary stenosis was made by Kan and her colleagues in 1982.¹² Since then, the technique has been accepted as a first-line treatment for congenital valvar pulmonary stenosis.^{42–45} Balloon dilation is usually indicated when the gradient across the stenosed valve is 50 mm Hg or more, or when there is an increase in right ventricular systolic pressure by more than half of the systemic pressure. The indications for the procedure are, however, different in neonates with a duct-dependent pulmonary circulation, when gradients are unreliable. A high right ventricular systolic pressure, and the presence of a dysplastic valve, is an accepted indication for treatment.

The right ventricular pressure is measured, following which right ventricular angiography is performed in the lateral projection in order to measure the diameter of the ventriculo-arterial junction at the basal attachment of the valvar leaflets. The stenotic pulmonary valve is crossed using an end-hole catheter, such as a multi-purpose catheter, a cobra-shaped catheter, or a Judkins right coronary arterial catheter. A guide-wire, from 0.014 to 0.035 inch in diameter, is passed through the catheter across the valve, and placed in a branch of the pulmonary artery supplying the lower lobe of either lung. In neonates, the guide-wire may be placed across the patent arterial duct into the descending aorta. A balloon that is about one-fifth to one-quarter larger than the diameter of the measured valve is passed through the sheath in the femoral vein over

the wire, and placed across the pulmonary valve. The balloon is rapidly inflated and deflated with dilute contrast across the stenosis. The balloon is then withdrawn, with the guide-wire still in place, and a catheter is passed into the pulmonary arteries to measure the persisting gradient. The Multitrack catheter designed by Bonhoeffer is very useful, as it allows measurement of both right ventricular pressure and the gradient across the pulmonary valve, coupled with the ability to perform angiography before and after dilation of the balloon without loss of position of the guide-wire. In patients with a very dysplastic pulmonary valve, balloons that are up to three-fifths larger than the diameter of the supporting subpulmonary infundibulum can be used, with acceptable relief of the stenosis. The technique of balloon dilation is more demanding in neonates. Although balloon dilation of pulmonary valvar stenosis carries low risks when performed in infants and children over the age of 1 year, there is a significant morbidity and mortality in the early neonatal period.^{46–48} In neonates, it is the size and function of the right ventricle that determine outcome. High right ventricular pressure, an irritable myocardium with a risk of arrhythmia, and splinting of the tricuspid valve, can all lead to haemodynamic instability. This necessitates very short periods of inflation, which may be helped by using balloons with low profile.

Adequate relief of the stenosis, with a reduction in the transvalvar gradient and in right ventricular systolic pressure, is achieved in the majority of patients.⁴⁹ Occasionally, however, there may be very little immediate reduction in gradient across the pulmonary valve. This is because of associated infundibular muscular stenosis, which disappears over a period in a similar fashion to that observed after surgical pulmonary valvotomy. Repeat balloon valvoplasty, after a few months, in those patients where the initial result was suboptimal, can produce a further reduction in gradient. Serious complications of balloon dilation include a tear of the pulmonary trunk, or perforation of the heart.^{50,51} In general, the complication rate, at 0.4%, is low, and reported mortality is no more than 0.2%.⁵² The consequences of chronic pulmonary regurgitation, nonetheless, can be underestimated, and more conservative dilation is now recommended.

Balloon dilation of the pulmonary valve can also be carried out as a palliative procedure in patients with tetralogy of Fallot and other complex congenital cardiac malformations. It can also be performed in patients with a functionally univentricular circulation to improve the size of the pulmonary arteries prior to staged palliations or repair. The basic principles of the procedure in these situations are the same as for isolated congenital valvar pulmonary stenosis, although crossing the stenotic subpulmonary outflow tract can be challenging. Problems with atrioventricular conduction can occur if the position of the atrioventricular bundle is abnormal. A more conservative approach is followed to avoid excessive flow of blood to the lungs, and to reduce the risk of pulmonary regurgitation. Reports have also emerged for dilation for infundibular stenosis using balloons, as palliative procedures, although without consistently desired results.

Valvar Pulmonary Atresia with Intact Ventricular Septum

The transcatheter interventions available to alter the course of this lesion (see also Chapter 30) include relief of right ventricular outflow obstruction with perforation of the

Figure 17-1 Images from a patient with pulmonary atresia with intact ventricular septum. A, Right ventricular contrast injection in lateral projection shows the atretic pulmonary valve (arrow). B, Simultaneous injection of contrast in the aorta delineates the pulmonary arterial surface of the atretic pulmonary valve (arrow) through a systemic-to-pulmonary artery shunt.

atretic valve and balloon dilation, stenting of the arterial duct to provide additional flow of blood to the lungs, enlargement of the atrial communication by balloon atrial septostomy to reduce right atrial hypertension, and occasionally, stenting of the subvalvar muscular right ventricular outflow tract in the setting of residual obstruction.

The success of interventional catheterisation, as determined by achieving a biventricular circulation, depends upon specific morphological characteristics. Patients should have a right ventricle with a tripartite cavity, a tricuspid valve with a diameter greater than 10 mm, or z score more than -1.5 , a pulmonary valvar and infundibular diameter more than 7 mm, and absence of right ventricular-dependent coronary arterial circulation.⁵³

The principles of catheterisation involve appropriate selection of patients, maintaining haemodynamic stability with ventilation, maintaining patency of the arterial duct with infusion of prostaglandins, careful catheterisation to avoid cardiac trauma or excessive bleeding through the catheter lumen, selection of the appropriate technique to perforate the atretic pulmonary valve, continuous monitoring of systemic arterial pressure, and anticipation and prompt management of pericardial tamponade by pericardiocentesis.

Antero-posterior and lateral projections of right and left ventricular angiography help confirm the absence of right ventricle-dependent coronary arterial circulation, delineate the right ventricular outflow and the pulmonary arterial end of the atretic valve, assess the left ventricle, and determine the morphology of the aorta and the arterial duct. Appropriate frames from the angiograms are fixed as reference images after identifying landmarks for perforation. An end-hole catheter with a curved tip, typically either cobra shaped or a Judkins right 3.5-cm curve, is used to achieve stable and precise position of the tip of the catheter in the right ventricular infundibulum, just beneath the atretic pulmonary valve. Clockwise rotation of the catheter hooks it around the ventriculo-infundibular fold, and directs the tip towards the right ventricular outflow tract. After pushing the catheter tip into the infundibulum, a counter-clockwise rotation engages it in most cases against the atretic pulmonary valve. Multiple angiograms

should be performed to confirm the position of the tip of the catheter, which will determine the site of perforation (Fig. 17-1A). By attaching a Tuohy-Borst Y connector to the hub of the catheter, biplane angiography can be performed with or without simultaneous aortography, thus delineating the right ventricular and pulmonary arterial surfaces of the atretic pulmonary valve (Fig. 17-1B). Once the position of the tip of the catheter against the atretic valve is satisfactory and stable, a radio-frequency wire connected to a generator is inserted into the guiding catheter. A commercially available radio-frequency perforation generator with a perforation catheter and co-axial injectable catheter, produced by the Bayliss Medical Company, is now available, and is most commonly used. This system is designed for tissue perforation and uses high voltage at 150 to 280 volts, with low power at 5 to 10 watts, to reach very high impedance, up to 7000 ohms, for short durations of application, from 1 to 5 seconds. An earthing plate is required, and should be placed under the buttocks before draping the patient. Care should be taken to avoid pooling of the antiseptic over this plate when the groin or umbilicus is prepared for access. A wire of 0.024-inch diameter, and 260-cm length, can be connected to a customised radio-frequency generator, which cuts off if the impedance exceeds the specified range. The wire has an exposed metal tip of 2 mm that is responsible for generating the thermal energy needed for the perforation. Rest of the wire is covered with Teflon. Repeated angiography should always be performed to confirm that the position of the catheter has not changed during loading of the perforating wire. The stiff-end of a coronary arterial wire, or a fibre-optic wire such as a 0.018- or 0.021-inch trimedyn wire connected to a Nd Yag or Excimer laser generator, may be used in place of the radio-frequency wire. After confirming the final position, perforation of the atretic pulmonary valve is carried out, taking extreme caution to prevent injury to the pulmonary trunk.⁵³⁻⁵⁸ The position of the radio-frequency wire beyond the perforated valve should again be confirmed before proceeding further. The position of the tip of the wire within the cardiac silhouette on both antero-posterior and lateral projections should raise suspicion of cardiac perforation suggesting that wire is in the pericardial space.

Figure 17-2 Radio-frequency perforation of atretic pulmonary valve. The lateral projection (A) shows perforation of the atretic pulmonary valve with a radio-frequency wire, followed by (B) insertion of a co-axial catheter over the radio-frequency wire, and (C) balloon dilation of the pulmonary valve. Note the abolition of the waist on the balloon.

In these circumstances, the wire should be promptly withdrawn and systemic arterial pressure should be monitored. If necessary, an echocardiogram should be performed to rule out cardiac tamponade. The hole made by the radio-frequency wire is usually very small, and unlikely to cause significant bleeding into the pericardial space. Once the atretic valve is successfully crossed, a fine catheter that can go over the wire is used, creating a co-axial system allowing for graded dilation of the pulmonary valve (Fig. 17-2). Various balloons are available to dilate the pulmonary valve. Pre-dilation with a small coronary arterial balloon of 2.5- to 4-mm diameter allows a larger balloon, of 7- to 10-mm diameter and 2-cm length, to be used effectively (Fig. 17-2C). An echocardiogram should be performed soon after the procedure to confirm adequate relief of right ventricular outflow obstruction. Pericardial effusion, if present, should be monitored closely after the procedure with invasive systemic arterial pressure monitoring and frequent echocardiography.

If adequate relief of obstruction has been achieved, the infusion of prostaglandin could be stopped to prevent the complications of systemic arterial steal from a large patent arterial duct. It is not, however, unusual to need prostaglandin for a few days to maintain adequate flow of blood to the lungs until right ventricular diastolic function improves, and there is effective antegrade flow across the right ventricular outflow tract. If weaning from prostaglandin fails to maintain systemic arterial saturations within an acceptable range, ductal stenting can be undertaken to provide additional pulmonary blood flow.⁵⁹ Ductal stents have a high risk of restenosis with intimal proliferation, and need close monitoring and anti-platelet therapy. Presence of infundibular muscle may contribute to dynamic obstruction after adequate relief of valvar stenosis. If severe, implantation of a stent into the outflow tract may also produce successful relief of obstruction.⁶⁰ In less severe situations, chronic treatment with oral β -blockade has been effective in providing adequate relief until regression of the muscular hypertrophy improves forward flow into the pulmonary arteries. During late follow-up, if despite an effective biventricular circulation, systemic arterial desaturation is observed due to right-to-left shunting, devices can be inserted to occlude the interatrial communication.⁶¹

Implantation of Pulmonary Valves

Bonhoeffer and his colleagues⁶² described the first implantation of a valve in the pulmonary position, placing the device through a catheter in a dysfunctional prosthetic conduit to relieve stenosis and regurgitation. The Medtronic Melody valve was made of a bovine jugular vein sutured

inside a balloon-expandable platinum-iridium stent, and was deployed using a custom-made system, now known as Ensemble, and produced by Medtronic Inc. The system contains a balloon-in-balloon catheter inside a long sheath with a dilator at the tip. Current systems have outer balloons of 18-, 20-, and 22-mm diameter. These balloons determine the final diameter of the implanted valved-stent, which should equal the diameter of the homograft conduit initially inserted surgically in the right ventricular outflow tract. The valve is suitable for insertion in right ventricular outflow tracts with diameters varying between 16 to 22 mm in patients with circumferential-valved conduits implanted surgically during their definitive repair. Magnetic resonance imaging helps to define the morphology of the outflow tract and the bifurcation of the pulmonary trunk, determine right ventricular volume and ejection fractions, and quantify the pulmonary regurgitant fraction. Echocardiography is used for surveillance and haemodynamic monitoring.

The procedure is performed under general anaesthesia. A balloon-tipped or curved-tip catheter is inserted through the femoral or jugular vein to access the distal left or right pulmonary artery with the aid of a floppy tipped Terumo wire. An Ultrastiff guide-wire, of 0.035-inch diameter and 260-cm length, with a pre-formed curve, is then positioned in one of the pulmonary arteries. A Multitrack catheter is passed over this stiff wire to measure right ventricular pressure, the gradient across the right ventricular outflow tract, and to perform angiography (Fig. 17-3A). Different projections are employed to define the morphology of the outflow tract, the bifurcation of the pulmonary arteries, and to assess the pulmonary regurgitation. Aortography performed through a pigtail catheter inserted into the femoral artery helps define the coronary arterial anatomy. If an anomalous course of a coronary artery is suspected, a selective injection into the artery, with simultaneous inflation of a balloon in the right ventricular outflow tract, is performed to rule out arterial compression. Once the outflow tract is deemed suitable for implantation, the valved-stent is washed in three different saline baths for 5 minutes each to wash off the glutaraldehyde preservative. The venepuncture is dilated in a graded fashion with 14 and 22 French dilators. The delivery system is thoroughly flushed, de-aired, and the inner and outer balloons prepared with syringes filled with diluted contrast, 10 mL for the inner balloon, and 20 mL for the outer balloon. The valved-stent is crimped on a 2.5-mL syringe by a gentle rolling action, and loaded on the balloon catheter. The outer sheath of the delivery system is brought gently over the crimped

Figure 17-3 The steps involved in percutaneous implantation of the pulmonary valve. A, The lateral projection of the pulmonary angiogram shows free pulmonary regurgitation through a Hancock conduit. B, Insertion of the Melody valve has resolved the problem.

valved-stent, ensuring complete covering of the proximal struts. The sheath is then slid over the entire length of the valved-stent, which is fully covered and ready to be inserted. The tip of the delivery system has a dilator, which provides a tapered tip to facilitate entry into the vein through the skin. The flexible delivery system can be looped in the right atrium to facilitate delivery of the valved-stent into an appropriate position. Standard principles of manipulation ensure delivery of the device in the right ventricular outflow tract without losing position of the wire. In patients with severe calcification and stenosis, pre-dilation with a high-pressure balloon, or pre-stenting with a bare metal stent, such as the Max LD, Intrastent, or Cheatham-Platinum stent, may be required. Once within the conduit, the valved-stent is uncovered by pulling back on the outer sheath. Angiography confirms satisfactory position of the valved-stent (Fig. 17-3B). Calcification of the conduit, or the bare stent itself, usually provides good landmarks for optimal positioning. The valve is deployed by sequentially inflating the inner and outer balloons. Haemodynamic assessment and angiography is then performed using the Multitrack catheter after implantation. In patients with a significant residual gradient, post-dilation with a high-pressure balloon may be required, using pressures of 10 to 12 atmospheres.

Implantation has now been carried out for dysfunction of the right ventricular outflow tract in patients with repaired tetralogy of Fallot and variants, transposed arterial trunks with ventricular septal defect and pulmonary stenosis, the Ross operation for left ventricular outflow disease, and repaired common arterial trunk.¹⁹ The majority of the patients had a homograft in the right ventricular outflow tract. There was a significant reduction in right ventricular systolic pressure, the gradient across the outflow tract, and improvement in pulmonary competence after valvar implantation, with no procedural mortality. Survival was 95.9% at 72 months.¹⁹ The incidence of complications decreased with subsequent implantations as a result of improvements in selection of patients and design of the device. Restenosis due to a hammock effect created by the venous wall hanging within the stent was not observed after these alterations in design. Fractures remain an important cause of restenosis, being seen after one-fifth of insertions, and can be managed with a second implantation within the initial one. Early detection, and anticipatory management,

of the fractured stent can be aided by chest radiography and echocardiography at regular intervals.⁶³

Adults who have undergone repair of the right ventricular outflow tract without use of a conduit, but have suffered aneurysmal dilation, are not suitable for implantation of the current device. Future research to design a device that can be implanted in larger right ventricular outflow tracts, more than 22 mm in diameter, is ongoing. Self-expanding stents designed to reduce the size of the dilated aneurysmal right ventricular outflow tract can hold the valved-stent within it to provide a secure anchoring mechanism.⁶⁴ These devices are likely to be most suited to treat isolated pulmonary regurgitation in dilated outflow tracts.

Aortic Valve

Aortic Stenosis

Balloon dilation of the aortic valve was first reported by Lababidi.⁶⁵ Currently accepted indications for intervention include the presence of a peak gradient greater than 70 mm Hg on Doppler with a left ventricular strain pattern on the electrocardiogram and symptoms such as syncope, effort intolerance, or angina. Neonatal indications for intervention are based on the presence of a duct-dependent systemic circulation, a low cardiac output state with severe left ventricular dysfunction, and a dysplastic stenotic aortic valve. Asymptomatic infants with congenital valvar aortic stenosis are treated for gradients greater than 50 mm Hg in the absence of a duct-dependent systemic circulation due to the risk of progression of the stenosis and development of left ventricular dysfunction. Since the original documentation, good results of balloon dilation of the aortic valve have been reported in both the short and medium term.^{66–68} There was some concern regarding femoral arterial occlusion, but this complication is less frequently seen now with the availability of low-profile balloons.

Parameters given consideration prior to the procedure, particularly in sick neonates with a low cardiac output, include achieving access, maintaining haemodynamic stability, ensuring hydration, adequate control of glycaemia and acid-base balance, ventilation, infusion of prostaglandin to maintain ductal patency, and appropriate cardiovascular drugs to maintain cardiac output. In infants and children, the procedure is performed under general anaesthesia. Heparin is used for anti-coagulation to prevent vascular thrombosis of the femoral artery or vein and systemic

thromboembolism. Avoidance of cooling and loss of blood during the procedure is very important to prevent haemodynamic compromise. The procedure can be performed through femoral arterial, femoral venous, umbilical arterial, axillary or carotid arterial access.^{31,67,69–71} The advent of rapid right ventricular pacing has reduced the need for an antegrade approach with trans-septal puncture with atrial septostomy. Femoral arterial puncture is used for monitoring of systemic arterial pressure when dilation is carried out antegrade through the femoral vein.

In haemodynamically stable patients, an angiogram is performed in the ascending aorta via a pigtail catheter profiled in antero-posterior and lateral projections. The aortic valvar leaflets are delineated, and the diameter of the ventriculo-arterial junction is measured and compared with those obtained on echocardiography, to avoid the risk of using an oversized balloon. Severe angulation of the left ventricular outflow tract can complicate accurate measurement of the valvar diameter. In haemodynamically unstable patients, angiography poses a risk of severe ventricular arrhythmia in the presence of left ventricular dysfunction. Hence, the diameter of the aortic valve as measured by echocardiography alone is used to determine the appropriate diameter of the balloon. Small sheaths, and catheters of 3 French diameter, are employed when using umbilical access in neonates, and 4 or 5 French catheters with angled-tip guide-wires are used in older children. A ratio of the diameter of the balloon to the outflow tract of 0.9 indicates an appropriately selected balloon, and is unlikely to cause significant regurgitation. An angiogram illustrating a jet of negative contrast through the stenotic valve serves as a reference to locate the effective orifice, which most commonly lies posteriorly and to the left in the aortic root. The valve is crossed in retrograde fashion using a curved-tip catheter, such as a Judkins right coronary catheter, a cobra-shaped catheter, or a cut-pigtail to provide a curved tip, and a floppy steerable guide-wire. Multiple rapid gentle stabs are made with the guide-wire to cross the valve. This step reduces the risk of perforating the valvar leaflets and traumatising the orifices of the coronary arteries.

When approaching in antegrade fashion, a Judkins right or a cobra-shaped balloon angiographic or wedge catheter is placed across the patent oval foramen and manoeuvred to enter the left ventricle through the mitral valve. Coronary wires are used in neonates and infants, and stiff exchange length wires are used in older patients requiring trans-septal puncture for antegrade access to the aortic valve. Similar stiff wires can be also used in the retrograde approach. The balloon-tipped catheters reduce the risk of passing through the intercaval spaces of the mitral valvar tension apparatus. A large curve is formed in the cavity of left ventricle to direct the tip of the catheter towards left ventricular outflow tract. A floppy steerable wire is then used to cross the aortic valve and achieve a good position in the descending aorta. The catheter is then threaded over the wire so that a stiff wire could be positioned for subsequent steps. Some authors believe that the antegrade approach offers a reduced risk of aortic regurgitation as a result of valvar perforation.

In patients with a low cardiac output, balloons remain stable during inflation across the stenotic aortic valve. In the absence of a state of low cardiac output, balloons can be mobile during ventricular systole, and can cause trauma

Figure 17-4 Retrograde aortic balloon valvoplasty with rapid right ventricular pacing as seen in frontal projection.

to the valvar leaflets. Stability is achieved using adenosine, and more commonly, rapid right ventricular apical pacing in older patients at fast rates of 180 to 220 beats per minute (Fig. 17-4). The antegrade approach leads to greater stability of the balloon, albeit that the risk of creating a tight loop across the atrial septum and the mitral valve increases the risk of severe haemodynamic compromise and cardiac trauma (Fig. 17-5). It is prudent to use a long balloon of 3.5 to 5 cm in older patients, as the left ventricle has a tendency to eject the balloon subsequent to inflation. Rapid inflation and deflation of the balloon are performed to minimise the duration of complete obstruction of flow through the valve.

Recent reports of long-term outcome after aortic balloon valvoplasty indicate that there is an excellent early relief of the valvar gradient, but an increase in aortic regurgitation.⁷² Independent predictors of unfavourable outcome have been a small aortic root, a valve with two leaflets, poor function of the left ventricle or mitral valve, and limited experience of the operator.⁷³ Procedure related mortality is reported at 4.8%.⁷³ Although the risk of vascular injury is high, the majority of the complications are transient, and respond to thrombolysis and anti-coagulation. In critical aortic stenosis, the morphology of the aortic root, the mitral valve and presence of left ventricular endocardial fibro-elastosis have a major impact on outcome and need for reintervention. Neonatal critical aortic stenosis remains challenging despite continuing development of catheter technology for small babies. Despite effective relief of stenosis, patients may require functionally univentricular palliation if the morphology is not favourable for effective biventricular circulations (see also Chapter 44).

Implantation of the Aortic Valve

Percutaneous interventions on the aortic valve in adults with calcific aortic valvar stenosis and other co-morbidities rendering the valve inoperable are encouraging. The

Figure 17-5 Anterograde balloon aortic valvoplasty. The balloon is introduced through the femoral vein and across the oval fossa defect, or after a trans-septal puncture, to access the left heart. The wire is placed in the descending aorta and provides stability to the balloon.

first report of insertion of bovine pericardial trifoliate valve came from Cribier and his colleagues.⁷⁴ Procedural complications in early implantations were related to the anterograde approach and the large size of the system required for delivery. The technique has been refined, with development of a retrograde approach, and implantation of the valve with rapid right ventricular pacing to reduce the risk of embolisation.²⁰ Self-expanding stent-mounted valves have also been used in similar clinical settings.⁷⁵ The current devices available, however, are not yet suitable for use in children and young adults.

Mitral Valve

Mitral Stenosis

Congenital mitral valvar stenosis is a complex disease, with involvement of supralvalvar, valvar and subvalvar components (see Chapter 35). Balloon dilation is rarely used as first intervention, due to the high risk of restenosis or risk of injury to the valvar tension apparatus and leaflets leading to severe regurgitation. Percutaneous valvoplasty, however, has successfully replaced closed and open mitral commissurotomy for rheumatic mitral stenosis. Selection of patients based on echocardiography is fundamental in predicting outcomes, and requires a detailed assessment of the mitral valve.⁷⁶

The approach is anterograde after trans-septal puncture. The Inoue balloon is most widely used, which consists of a coaxial balloon with a double lumen. Inflation leads to sequential dilation of the distal part, facilitating entry into the left ventricle, of the proximal part fixing the balloon across the mitral valve, and of the central part, which dilates the valvar annulus. A Multitrack technique with a mono-rail system with two balloons over a single guide-wire was introduced by Bonhoeffer and colleagues,³⁸ permitting successful dilation of the fused leaflets of the mitral valve.

Mitral Regurgitation

Percutaneous transcatheter interventions on the mitral valve to treat mitral regurgitation are being investigated in adults, permitting clipping or suture of the leaflets to produce dual orifices, or by inserting devices within the coronary sinus to improve coaptation of the leaflets.^{23,24}

Tricuspid Valve

Congenital tricuspid valvar stenosis rarely occurs as an isolated lesion, and is most commonly associated with hypoplasia of the components of the right heart. Acquired stenosis in children is almost always due to rheumatic disease, and virtually never occurs as an isolated lesion.

Balloon dilation of the stenotic tricuspid valve has been reported in parts of the world with high prevalence of rheumatic fever. The basic principles of the techniques used are similar to those applied for mitral stenosis. The Inoue balloon is most commonly used, albeit that double balloons can be used. In congenital lesions, the associated hypoplasia of the right heart usually takes precedence in making management decisions.

Shunts

Atrial Septal Defects

Interventional catheterisation is the first modality of treatment to close defects in the atrial septum when increased pulmonary blood flow has caused dilation of the right heart. The morphology of the defect determines the suitability of the technique, those most suitable being the ones within the oval fossa with adequate margins at the rims. Superior and inferior sinus venosus communications, those defects in the oval fossa with deficient or floppy margins, or large defects encroaching on surrounding structures or resulting in haemodynamic compromise or trauma, are the general contraindications. Any associated lesions, such as anomalous pulmonary venous drainage, should be ruled out.

There are many devices available to close the defects, and they vary in their ease of loading and deployment, their suitability for the morphology of the defect, along with safety, efficacy and long-term behaviour. The most commonly used Amplatzer atrial septal occluder consists of two discs of Nitinol wire mesh connected by a waist of 4 mm thickness, which forms the central occluding disc (Fig. 17-6). The device is available in different sizes depending upon the diameter of the central disc. The left atrial disc is larger than the central occluding disc by 12 to 16 mm. A new Cribiform device is now available for closure of multi-fenestrated defects. This device has a much narrower waist to position it through one of the central defects, with the left and right atrial discs covering the surrounding holes. A Dacron polyester patch is sewn into the device to increase thrombogenicity. The delivery system consists of a loading sheath to help collapse the device and load it into a long delivery sheath attached to a delivery cable. The long sheath is angled at 45 degrees and has varying diameters and lengths. The device is attached to the delivery cable with a screw-on mechanism allowing release of the device after satisfactory deployment. Rates of closure are excellent when patients are selected in appropriate fashion.

The procedure is performed under general or local anaesthesia with sedation. Availability of trans-thoracic, trans-oesophageal, and intracardiac echocardiography has been crucial to the safety and success of the procedure. A catheter

Figure 17-6 The Amplatzer septal occluder, with the left and right atrial discs connected by a waist. The device is attached to a cable which is inserted through a delivery sheath. (Reproduced with permission from Seivert H, Qureshi SA, Wilson N, Hijazi ZM [eds]: *Percutaneous Interventions for Congenital Heart Disease*. London: Informa Healthcare, 2007, Figure 28.1.)

passed through the femoral vein is used to position the sheath across the defect. The pulmonary vein is used as the site for anchorage of a stiff guide-wire. Initially, complications of embolisation led operators to use large devices. The defect is sized using pulmonary arterial angiography, echocardiography, or with a contrast-filled balloon stretched across the defect (Fig. 17-7A). Care must be taken to avoid stretching the defect.⁷⁷ Colour flow mapping and occlusion of flow by inflating a balloon, the stop-flow technique, are also used as techniques for sizing. A device of size equal to or just larger than the size of the defect is commonly used. It is delivered through the sheath across the defect under fluoroscopic and echocardiographic guidance, ensuring appropriate deployment, absence of obstruction to contiguous structures, and lack of residual shunting (Fig. 17-7B). Successful anchorage is checked by wiggling the device whilst it is still attached to the delivery system, thus ensuring a secure position. The device can be retrieved and redeployed to the satisfaction of the operator prior to release. Various techniques used to deploy devices in larger defects

include the use of specially designed sheaths with a double curve, a sheath positioned in the right upper pulmonary vein, a dilator, or balloon-assisted techniques that prevent prolapse of the left atrial disc across the defect.

Complications of the procedure include trauma leading to tamponade, embolisation, thrombosis, endocarditis, and arrhythmias. Recently, concerns have been raised about late cardiac perforations after use of the Amplatzer occluders.^{78,79} The risk of erosion, however, has been low, as confirmed by the registry for adverse events in clinical trials in the United States of America and in other countries.⁷⁷ Patients with a deficient aortic rim, and/or a deficient superior rim, of the oval fossa may have a higher risk of erosion. Those patients who present with a pericardial effusion within 24 hours should be monitored closely, and may require removal of the device surgically should there be an increase in the effusion.

Other devices available to close atrial septal defects include the CardioSEAL and STARflex devices, based on the double umbrella design, and with struts made from a cobalt alloy.⁸⁰ The Helex device is a new concept with a helical arrangement of a long Nitinol wire to which is attached a long curtain of expanded polytetrafluoroethylene.⁸¹ When deployed, two circular discs form at each end of a flat helix, the curtain covering the septal defect. By pulling on the suture connecting the right atrial disc to the inner catheter of the delivery system, the whole device uncoils from its circular shape, and can be retrieved even after deployment into the delivery system (Fig. 17-8). A button device, and more recently, a frameless occlusion device, have also been described for use in defects without adequate rims.⁸²

Ventricular Septal Defects

Closure of ventricular septal defects was first performed subsequent to myocardial infarction, or for congenital defects, using the Rashkind double-umbrella devices.⁸³ The current device of choice is the Amplatzer ventricular septal defect occluder, although various other devices have been used over the years.

The designs of the Amplatzer device can be tailored according to the morphology of the ventricular septal defect. The device used for perimembranous defects has a special asymmetrical shape with a very short waist, which forms the occluding part of the device. The left-sided disc has a deficient cephalad margin to avoid

Figure 17-7 Closure of an atrial septal defect closure with the Amplatzer septal occluder. A, Balloon sizing of the defect. The current guidelines suggest use of stop-flow technique, rather than over-stretch the defect margins. B, The Amplatzer device before release.

Figure 17-8 The Helix atrial septal occluder after deployment, when it is still retrievable.

contact with the aortic valve, and a platinum marker diametrically opposite, on the caudal margin, to help orientate the device correctly. Orientation is achieved using a custom-made delivery system that has a flattened segment on the circumference of the micro-screw, to which the device is attached before loading. Occluders designed for muscular defects have a longer waist depending on the size of the occluder, which varies from 6 to 24 mm in diameter (Fig. 17-9). The device is sized on the basis of the diameter of the occluding part, which is its waist.

Haemodynamic assessment is performed to quantify the shunt and demonstrate a restrictive defect. Angiography in the long axial oblique view usually defines the location and the size of a perimembranous defect.

Transoesophageal echocardiography, with views between 0 and 30 degrees and longitudinal views between 90 and 120 degrees, are best suited to define the morphology of these defects. The defect is crossed from the left ventricular side with a curved tip catheter and a glide wire, which is positioned in either the superior caval vein or the pulmonary artery. The glide wire is then exchanged with a special wire, the so-called noodle wire from AGA Medical, which is snared using a goose-neck snare from the femoral vein, and exteriorised to form an arterio-venous loop. The delivery sheath is loaded over this wire and positioned across the defect. When the defect is perimembranous, the sheath may have to be positioned in the left ventricular apex by careful manipulation in tandem with the guide-wire and the catheter. The device is deployed under fluoroscopic and echocardiographic guidance. Before release, left ventricular angiography and echocardiography help confirm a good position and secure anchorage (Fig. 17-10). Continuous monitoring of atrioventricular conduction is vital during occlusion of perimembranous defects. Persistent complete heart block is an indication either for redeployment or abandonment of the procedure.

Complications of this intervention include embolisation of the device, haemolysis, thrombo-embolism, tricuspid, and aortic regurgitation. Late complete heart block, reported particularly in perimembranous defects^{84,85} due to the proximity with the conduction tissue, use of oversized devices to reduce the risk of embolisation, and continued expansion of the device, have been treated with high dose steroids and aspirin. A future review of the design of devices used to close perimembranous defects may help match the high standards of results achieved after surgical closure, and the low risks of complication of the surgical approach, such as the need for cardio-pulmonary bypass, heart block, residual defects, and mortality.

The principles for closure of muscular defects are similar to those for perimembranous defects. Single muscular defects may be crossed from the right ventricular aspect without the need for an arterio-venous loop. Apical defects may be crossed easily from a jugular approach, and outlet defects from a femoral approach. Angiography and echocardiography aid in appropriate positioning of the device (Fig. 17-11).

Figure 17-10 Closure of perimembranous ventricular septal defect with Amplatz membranous septal occluder. A, Long axial oblique projections show the left ventriculogram with the device in the defect and no residual shunt before release. B, The aortogram after release shows no aortic regurgitation. The orientation of the device is clearly seen, with a flattened margin to the left ventricular disc to prevent aortic valvar injury, and a platinum marker diametrically opposite to it.

Interventions on the Intact Atrial Septum

The creation of an 'atrial septal defect without thoracotomy or anaesthesia' as described by Rashkind and his colleagues was the first intervention reported on the atrial septum, and as explained in our introduction, represented the birth of interventional catheterisation.³ Enlargement of a naturally occurring atrial communication is performed in patients with transposition to improve mixing. In other conditions, such as tricuspid atresia, double inlet ventricle with hypoplastic left or right atrioventricular valves, hypoplastic left heart syndrome, and others with the Fontan circulation, atrial septostomy is performed to relieve left or right atrial hypertension. Patients with left ventricular failure who are supported by extracorporeal membrane oxygenation may also need trans-septal puncture and atrial septostomy.

In patients with a patent oval foramen or a restrictive atrial communication, pull-back of a balloon catheter filled with saline or contrast (Fig. 17-12), or static balloon

atrial septoplasty, increases the size of the interatrial communication. The flap valve of the oval fossa can be torn to enlarge the defect in a graded manner by increasing the volume of contrast or saline in the balloon. Access to the atrium may be through umbilical, femoral or hepatic veins. In neonates, this procedure can be performed even on the intensive care unit under trans-thoracic echocardiographic guidance. In patients with an intact atrial septum, a trans-septal atrial puncture is performed to gain access to left-sided structures. The use of the trans-septal needle requires experience with fluoroscopic and echocardiographic guidance. A Brockenbrough needle is used within a long sheath and dilator. The length of the needle tip protruding from the dilator should be marked by noting the distance of the proximal flange of the needle from the hub of the dilator within the sheath. The arrow on the flange, and its alignment to the needle tip, should also be checked before inserting the needle into the right heart. The long sheath with the dilator is inserted over a guide-wire to position the tip of the dilator in the superior caval vein. The wire is replaced with the trans-septal needle with its tip still sheathed in the

Figure 17-12 Balloon atrial septostomy by the pull-back technique. The balloon, filled with contrast, is pulled back from the left to the right atrium to enlarge the atrial communication.

Figure 17-13 A, Trans-septal puncture used to decompress the left heart in a patient with dilated cardiomyopathy on extra-corporeal membrane oxygenation, illustrating fluoroscopy on frontal projection and trans-oesophageal echocardiography (probe seen). B, A static balloon dilation used to enlarge the atrial septal puncture. C, Blade atrial septostomy, with the Park blade catheter open with the blade at an angle of 45 degrees.

Figure 17-14 A, Paravalvar leak from a prosthetic aortic valve. Balloon sizing (B) is followed (C) by occlusion with the Amplatzer duct occluder.

dilator. Using echocardiography and fluoroscopy in frontal and lateral projections, the whole assembly is slid down into the oval fossa, indicated by stepping over the superior limb of the margin of the oval fossa. A pigtail catheter placed in the non-coronary sinus of the aortic valve helps to identify the posterior wall of the aorta. Once the needle tip is engaged in the fossa, the septum can be stained with contrast and tented by pushing (Fig. 17-13A). A change in the waveform from right to left atrial pressure traces, injection of contrast in the left atrium, and echocardiographic and fluoroscopic guidance, all indicate entry into the left atrium. The needle should then be covered with the dilator and the sheath at all times to prevent trauma to the left atrial wall. Depending upon the indication for trans-septal puncture, the needle could be exchanged for other catheters or guide-wires. Diligent de-airing manoeuvres and anti-coagulation are required whenever operating in the left atrium and systemic circulation. Static or pull-back balloon angioplasty is then performed to create an adequate atrial communication (Fig. 17-13B). In some instances, when the atrial septum is very thick, the use of a blade catheter facilitates septostomy (Fig. 17-13C).

A newer method of creating an atrial fenestration is the use of radio-frequency wires.⁸⁶ Defects created by static balloon septoplasty, or pull-back septostomy, tend to close spontaneously within weeks or months, particularly in those with a thickened atrial septum, with a limited flap valve in the oval fossa. Various methods to keep the defect patent have been attempted, including implantation of stents and the use of fenestrated devices for atrial septal closure.^{87,88}

Para-valvar Leaks

Para-valvar leaks around surgically implanted prosthetic valves in aortic or mitral position may lead to haemodynamically significant valvar regurgitation or chronic

haemolysis, anaemia, and jaundice. The leaks may be single or multiple, circular or crescentic in shape, and may sometimes extend all around the circumference of the valve. Various devices have been used to close these leaks, including the Rashkind double umbrella device, the Amplatzer ductal occluder, or vascular plug and coils.

For aortic para-valvar leaks, femoral arterial access is used to perform an aortogram to identify the leaks, and confirm that the origins of the coronary arteries are not in close approximation (Fig. 17-14A). The leak is crossed with an angled wire placed through a Judkins right coronary arterial catheter, and then exchanged with a stiff 0.035-inch diameter wire, which is positioned in the left ventricle. A balloon catheter is passed over the stiff wire to size the leak (Fig. 17-14B). An Amplatzer ductal occluder is usually the most appropriate device for para-aortic leaks (Fig. 17-14C). The device is delivered through a long sheath. Before release, it is necessary to confirm free movement of the valvar leaflets, and unobstructed flow into the coronary arteries.

For mitral para-valvar leaks, trans-septal puncture is necessary either to cross the leak from left atrium, or to snare a guide-wire passed from the left ventricle to the left atrium through retrograde arterial access. The device is delivered through the left atrium after forming an arterio-venous loop, which is exteriorised on the venous side through the femoral or jugular vein.

EXTRACARDIAC INTERVENTIONS

Shunts

Patent Arterial Duct

Techniques for occlusion of the persistently patent arterial duct have come a long way since the first use of Ivilon plugs. The most common devices used are detachable coils for small ducts, and the Amplatzer ductal occluder for larger defects. Access to the duct can be antegrade

or retrograde. Use of oximetry to quantitate the shunt is not useful, and the decision for intervention relies upon echocardiography. Angiography in right anterior oblique and lateral projections profiles the length of the duct adequately. The smallest diameter along the length of the duct is used to determine suitability for interventional closure. The presence of a long restrictive duct with a good aortic ampulla is most suitable for transcatheter occlusion. Small residual leaks at the end of the procedure, particularly after occlusion with coils, close over time during follow-up.

Ducts that are less than 3 mm diameter in infants and young children, and less than 5 mm in older children, may be closed with a coil. Multiple techniques are available for use in older patients. Various coils are available depending on the diameter of the wire, the diameter of the coil when formed, and the length of the coil. Delivery of the coil can be achieved by pushing it out of the catheter with a guide-wire, as with the Gianturco system, or by using the delivery cable to which they are screwed, as with the Flipper device. The diameter of the coil should be twice the smallest diameter of the duct. Retrograde delivery is performed with the use of small catheters, with not more than three-quarters of the coil loop on the pulmonary arterial side, and the remaining loops within the aortic ampulla. No part of the loop should be hanging in the aortic lumen. Care is also taken to avoid overhanging of the origin of the left pulmonary artery, particularly in young infants (Fig. 17-15).

The most common device used for closing larger ducts, those greater than 4 mm diameter, is the Amplatz ductal occluder, made of Nitinol wire woven into a cylindrical shape with a retention disc 4 mm larger than the diameter of the device. It is available in different sizes based on the diameter of the cylindrical occluding parts at the aortic and pulmonary ends, respectively. Delivery of the device is through a long sheath with a delivery cable, which has a male end screwed on to the female thread that is welded

to the pulmonary arterial end of the device. Due to this arrangement, delivery of this device is always antegrade with venous access. Arterial access is also used to perform aortography before and after closure. The device is deployed under fluoroscopy, with the aortic retention disc in the descending aorta. The assembly, including the sheath, the delivery cable and the device, are pulled back as one unit to engage the device into the aortic ampulla. The tracheal air column, and the tugging sensation experienced during delivery, provide useful landmarks for optimal delivery and positioning within the duct. The sheath is then pulled back over the device to release it across the narrowest diameter of the duct with a slight tension on the cable. An aortogram is repeated to confirm appropriate positioning of the device, and to rule out aortic or pulmonary arterial obstruction. (Fig. 17-16). It is common to have some contrast go through the device. If the position is not satisfactory, it is possible to retrieve the device into the sheath, and either redeploy or replace it with a device of more appropriate size. Angled devices, with a concave aortic rim at an angle to the occluding part, designed to prevent protrusion into the aortic lumen, may reduce the risk of aortic obstruction.⁸⁹ Multiple coils delivered with snares or bioprotomes have been used in ducts of moderate size.⁹⁰

Risks of this procedure are low in older infants and children. Residual leaks, haemolysis, or obstruction of a pulmonary artery or the aorta may occur when either coils or the ductal occluder are used. Embolisation to the pulmonary or systemic circulation can occur if the ducts are not sized appropriately. Removal of the device can be achieved by using a snare inserted through a long sheath. Late dislodgement and migration are rare. Should they occur, then surgical removal is needed. There have been no well-designed trials, to date, truly comparing the outcome of various devices.

Figure 17-15 Occlusion of a patent arterial duct with multiple coils.

Figure 17-17 Balloon angioplasty of recoarctation. A, The lateral projection of the aortogram shows stenosis after a subclavian flap surgical angioplasty for coarctation. B, The result of balloon angioplasty, with abolition of the waist.

Aorto-pulmonary Window

The closure of small aorto-pulmonary defects was successfully attempted with the Rashkind double umbrella device.⁹¹ The Amplatz group of occluders have also been used to close aorto-pulmonary windows, either as the primary procedure or to close residual defects after surgery.^{92,93}

Arterial and Venous Obstructions

Coarctation of the Aorta

Balloon Angioplasty

Experimental angioplasty by Lock and his colleagues¹⁰ heralded the clinical application of this technique for coarctation, while the technique first described by Singer and colleagues⁹⁴ is a widely accepted treatment for recoarctation, although a controversial treatment of native coarctation.

The procedure is performed under general anaesthesia. A haemodynamic assessment of the lesion is made through femoral access using a Multitrack catheter over a guide-wire placed in the left or right subclavian artery or within the left ventricle. Angiography is performed to measure the diameter and length of the stenosis, the proximal and distal segment of the aorta, to determine the size of the balloon, and identify presence of aneurysms from previous surgical repair. The size of the balloon is chosen to equal the proximal transverse arch, or a size is chosen not greater than three times the size of the lesion, but less than the diameter of the descending aorta at its position close to the diaphragm (Figs. 17-17 and 17-18). The Multitrack system is versatile enough to allow all procedures subsequent to dilation, avoiding recrossing of the freshly dilated site with a wire or a catheter. Risks of the procedure, particularly for those with native coarctation, include rupture of the aorta and aneurysmal formation. Presence of postoperative scar tissue makes the aorta less susceptible to disruption.

Early results of balloon angioplasty for native coarctation in infants as a temporising measure before definitive surgical intervention have been encouraging. Effective short-term palliation was reported in nine-tenths of infants less than 3 months of age, albeit that half developed recoarctation during follow-up, and required repeated intervention or surgery.⁹⁵ Balloon angioplasty has been shown to be as successful as surgery for native coarctation

in selected children and adults, but for recoarctation, balloon angioplasty was more successful in children than in adults.⁹⁶

Stent Angioplasty

The advent of stent angioplasty has challenged the usefulness of balloon angioplasty in coarctation of the aorta. Stent angioplasty is performed for both native and recoarctation of the aorta, predominantly in older patients. Its use in infants and young children is limited by the size of stents available, and their lack of growth, albeit that stent angioplasty has been used for obstruction of the arch after the Norwood operation for hypoplastic left heart syndrome⁹⁷ (Fig. 17-19). Stents provide a more effective relief of stenosis, reduce the risk of restenosis, injury to the aortic wall, and aneurysmal formation.⁹⁸ The size of the balloon is chosen using the same principles as applied for standard angioplasty, and the length of the stent is determined by the length of the stenosis. Stents should be long enough to cover the stenotic segment, extending at least

Figure 17-18 The lateral projection of an aortogram showing (A) recoarctation after end-to-end anastomosis for aortic coarctation, (B) relieved by balloon angioplasty.

Figure 17-19 Stent angioplasty for recoarctation after Norwood operation in frontal projection aortography.

15 mm beyond the stenosis, without covering the origins of the arterial branches arising from the aortic arch. Various stents of different designs are currently available for use in the aorta, including the Palmaz, Cheatham-Platinum, and Intrastent variants.

Insertion of the stents has produced satisfactory relief of the gradient across the stenosis, with increase in the diameter of the coarcted segment, and with only minor complications.⁹⁹ Some have reported aneurysmal formation,¹⁰⁰ while others have noted greater reduction in gradient, lower residual gradients, and a larger diameter of the coarcted segment when comparing stent angioplasty with balloon angioplasty.¹⁰¹ Use of balloon-in-balloon catheters (Fig. 17-20), graded dilation, and right ventricular pacing (Fig. 17-21) at the time of implantation, has reduced the

rate of complications. Covered stents (Fig. 17-22) used for complex coarctation and near-atretic lesions have reduced the consequences of dissection or rupture. The use of polytetrafluoroethylene-coated Cheatham platinum stents has also significantly reduced the systolic gradient across the coarctation, and increased the diameter of the coarctation.¹⁰² Despite advances in techniques, and availability of covered stents, the risk of aortic rupture, dissection, and aneurysmal formation may never be completely abolished.

Pulmonary Arterial Stenosis

Pulmonary arterial stenosis may be caused by postsurgical scarring after palliation or repair of congenitally malformed hearts, as in tetralogy of Fallot, a distally migrated pulmonary arterial band, or after the LeCompte manoeuvre as part of an arterial switch operation. Arteriopathy related to genetic factors include elastin gene mutations in Williams syndrome, Alagille syndrome, and congenital rubella syndrome, and tend to be more widespread and associated with diffuse hypoplasia of the pulmonary arterial tree. Pulmonary arterial hypoplasia due to diminished flow necessitates surgery, involving either a systemic-to-pulmonary arterial shunt or a patch across the right ventricular outflow tract extending onto the pulmonary arteries. Extension of ductal tissue to a pulmonary artery may also cause constriction in postnatal life, needing augmentation with a patch. The risk of restenosis remains high. Palliative surgery leading to a Fontan circulation often involves multiple interventions on the pulmonary arteries.

Pulmonary Arterial Balloon Angioplasty

Indications for angioplasty when the right ventricular pressures are normal or only mildly elevated are controversial. In infants and children, however, significantly diminished perfusion to one lung in spite of a normal right ventricular pressure is an accepted indication for intervention. More aggression may be needed in patients requiring staged palliation culminating in Fontan circulation in order to have good sized pulmonary arteries despite small gradients. Overall, accepted indications for balloon angioplasty include right ventricular hypertension, right ventricular dysfunction, perfusion mismatch, with less than one-quarter of flow directed to one lung, pulmonary hypertension in the unaffected lung, or presence of severe pulmonary regurgitation.¹⁰³

Figure 17-20 Balloon-in-balloon catheter used for stent angioplasty with (A) the inner balloon inflated first and (B) the outer balloon inflated to deploy the stent.

Figure 17-21 Stent angioplasty of native coarctation. A, Native coarctation of aorta, treated by graded dilation with stent angioplasty (B and C) to reduce the risk of aortic dissection or aneurysmal formation.

Figure 17-22 The covered Cheatham Platinum stent. (Reproduced with permission from Seivert H, Qureshi SA, Wilson N, Hijazi ZM [eds]: *Percutaneous Interventions for Congenital Heart Disease*. London: Informa Healthcare, 2007, Figure 53.1.)

The basic principles of balloon angioplasty are applied. After haemodynamic stabilisation, a stiff wire position is achieved in a good distal vessel of the lung. Angiography is performed and the size and length of stenosis are measured. The Multitrack catheter is useful for multiple haemodynamic measurements and performing angiography. The diameter of the balloon is determined by the diameter of a normal vessel adjacent to the stenosis. A higher ratio of balloon-to-stenosis diameter increases the chance of success, but also the risk of dissection, rupture, or aneurysmal formation. The success rate in one series was higher when the diameter of the balloon was more than 3 times the diameter of the stenosis, with a significantly greater diameter achieved after the procedure.¹⁰⁴ Outcome is assessed by an increase in the diameter by more than half, a reduction of the ratio of right ventricular to systemic arterial pressures, or by assessment of distribution of perfusion to the lungs.

Complications are more frequent after dilation of tight stenoses requiring oversized balloons and high pressures of inflation. Stenoses were impossible to dilate in half the patients on one series, with recurrent stenoses occurring in up to one-third.¹⁰⁵ The Valvuloplasty and Angioplasty registry documents an incidence of complications on one-eighth of patients, including rupture of vessels and death. Success has been achieved in two-thirds of patients unresponsive to conventional angioplasty by using high-pressure balloons.³⁴ Trauma can also be produced to the pulmonary arteries, usually with the tear occurring distal to the area of the stenosis.¹⁰⁶ Pulmonary hypertension was found to be a significant risk factor for such trauma.

Cutting balloons, as produced by Boston Scientific (Fig. 17-23), and used successfully in resistant coronary and peripheral arterial lesions, are now being used for resistant stenotic lesions in the pulmonary arteries that are undilatable even at high pressures. The balloon has three or four microtome blades, attached along the length of the balloon, that protrude on inflation to create controlled

Figure 17-23 A cutting balloon with microtome blades. cuts on the walls of the stenosed vessels. On deflation, the balloon folds over the blades. Early results in lesions resistant to conventional balloon angioplasty have been encouraging.^{107,108} Overall, cutting balloons improve the gain in luminal diameter, albeit with a slight increased risk of vascular trauma.

Pulmonary Arterial Stenting

Endovascular stenting has been increasingly used in older patients, and in haemodynamically significant stenosis in infants and young children. Stents are particularly effective in abolishing stenosis that reappears after successful balloon angioplasty due to elastic recoil and for dynamic stenosis related to folds and kinks in surgically repaired pulmonary arteries.¹⁰⁹

Stenting of complex stenoses involving the pulmonary arterial bifurcation remains a challenging procedure (Fig. 17-24). Due to close proximity of the origins of the right and left pulmonary arteries, it is advisable to deploy stents simultaneously into both arteries. In patients who have undergone the LeCompte manoeuvre as part of the arterial switch operation, the pulmonary arterial bifurcation lies anterior to the ascending aorta. Coronary arteries that have been transferred during arterial switch may be in close proximity to the site of implantation of stents, and the risk of arterial occlusion should be considered.

Systemic Venous or Baffle Stenosis

Stenosis of major systemic veins, such as the superior or inferior caval vein, may be seen after injury due to cannulation in neonates or infants undergoing cardiopulmonary bypass. Systemic venous baffles constructed surgically to redirect systemic venous flow for repair of complex congenital heart disease may also develop obstruction

Figure 17-24 Bilateral pulmonary arterial stenting for stenosis at the bifurcation of the pulmonary trunk. Simultaneous inflation of balloons in both pulmonary arteries. The left anterior oblique projection with a cranial tilt profiles well the pulmonary arterial bifurcation.

Figure 17-25 Systemic venous obstruction, with stents implanted in the obstructed superior and inferior caval pathways in a patient with a Mustard procedure.

during late follow-up. Systemic venous connections to the pulmonary circulation, which are direct, such as a superior cavopulmonary anastomosis, or through a conduit, as in the inferior cavopulmonary anastomosis, may develop stenosis with important consequences. With the advent of the arterial switch operation, the use of intra-atrial baffles for redirection of systemic veins is now used for treatment of complex lesions with abnormal systemic venous drainage in the context of isomerism, or with the double-switch operation for those with congenitally corrected transposition. The long-term survivors of Mustard and Senning operations, nonetheless, are now seen in the clinics for adults with congenital heart disease, and this intervention may be most often required in this population. Obstruction of the superior or inferior caval venous pathway may remain silent, with formation of collateral venous channels, and only be detected during routine investigations, or during placement of the permanent pacemaker because of sinus nodal dysfunction. Similarly, presence of collateral circulation may mask any pressure gradients in systemic venous baffles or conduits.

Obstruction to systemic venous drainage can be treated with balloon dilation as a palliative measure in young infants or children, or with stenting for older patients, with good long-term outcome. Angiography to delineate the stenosis is a very important step in planning the treatment. If stenosis is severe, access may be required from both ends with cannulation of femoral and jugular veins. Very thin wires may be used to cross the lesion. If there is atresia, the Brockenbrough needle may have to be used. Long sheaths are then used to cross the stenotic segment and an appropriate stent is deployed. Balloon expandable (Fig. 17-25) and self-expanding stents have also been successfully used to relieve obstruction, with good long-term results.¹¹⁰⁻¹¹² Transvenous pacing has also been successfully achieved through the stents.

Pulmonary Venous Stenosis

Pulmonary venous stenosis can be isolated, or can follow repair of anomalous pulmonary venous drainage, with or without other congenital cardiac disease. There has been an increasing awareness of the condition as an isolated entity, particularly, in premature infants. In infants and children, pulmonary hypertension and right-sided cardiac failure manifest over time. In adults, the aetiology may be compression by a mediastinal or pulmonary malignant neoplasm, or following interventional or surgical treatment of atrial arrhythmia. In both the congenital and acquired forms of pulmonary venous stenosis, histological findings show neo-intimal proliferation leading to occlusion of the lumen of one or more pulmonary veins.

Angioplasty and stenting of pulmonary veins are increasingly performed to treat this difficult disease. Access to the pulmonary vein is through the patent oval foramen or after trans-septal atrial puncture. A guide catheter is commonly used over a 0.014-inch coronary arterial wire if a coronary arterial or a cutting balloon is used. Angioplasty with a cutting balloon is usually followed by conventional balloon angioplasty, with or without stenting. Anti-coagulation is used during follow-up to prevent in-stent thrombosis. Failure of angioplasty, and occurrence of in-stent stenosis after stent angioplasty, are probably explained by the progressive neo-intimal proliferation.¹¹³ Cutting balloons have been used with encouraging results, albeit that the disease substrate is progressive, and long-term benefit remains unknown.¹¹⁴ Drug-eluting stents, and concomitant use of oral agents such as sirolimus, are being used to treat this fascinating and frustrating disease.¹¹⁵ Intrastent sonotherapy has been used to treat restenosis.¹¹⁶

Stenting of the Arterial Duct

Stenting of arterial duct for duct-dependent systemic and pulmonary circulations has made a resurgence with improvements in technology and advances in interventional

Figure 17-26 Ductal stenting in a patient with pulmonary atresia, intact ventricular septum. A, The lateral projection of the aortogram outlines the restrictive arterial duct. B, The stent is positioned in the arterial duct from the pulmonary artery with check aortography. C, There is good flow through the duct after implantation.

catheterisation. Patients with pulmonary atresia and intact ventricular septum amenable to transcatheter perforation of atretic pulmonary valve may need augmentation of pulmonary flow until right ventricular diastolic function, and hence filling, improves and effective forward flow can be established across the pulmonary valve. Ductal stenting as a part of hybrid procedure in hypoplastic left heart syndrome is based on similar principles. The most commonly used stents are pre-mounted coronary arterial stents 3 to 4 mm diameter, and 12 to 24 mm in length. Based on previous surgical experience, the diameter of the ductal stent is chosen to be smaller than that of a comparable modified Blalock shunt suitable for the weight of the patient. The small diameter of the stent reduces the risk of pulmonary over-perfusion.

The procedure is performed under general anaesthesia. The duct needs to constrict in order to provide a good grip on the stent, and this may require cessation of prostaglandin for at least 6 hours prior to procedure. Venous access is employed for delivery of the stent, and arterial access for angiography and monitoring of arterial pressures. Aortography is performed to identify ductal morphology, noting its diameter and length, and to identify landmarks for implantation of the stent (Fig. 17-26). A coronary arterial guide-wire is passed through the duct, and the stent is delivered through a coronary guide catheter, or directly over the wire. Angiography is performed from the aorta, or through the coronary guide catheter, to confirm a satisfactory position of the duct. The length of the stent is usually 1 to 2 mm longer than the ductal length, so as to cover the pulmonary arterial end of the duct. Compression of the origin of the pulmonary arteries, and protrusion of the stent into the descending aorta, are diligently avoided. After deployment, aortography confirms the adequate patency of the duct and the stent. Prostaglandin is then discontinued, and the patient is commenced on an anti-platelet dose of aspirin. Risks associated with stenting of the arterial duct include thrombosis and intimal proliferation, occasionally requiring redilation.^{117,118}

Removal of Foreign Bodies or Devices from the Circulation

With the widespread use of in-dwelling central venous catheters for chemotherapy, hyperalimentation, and monitoring, and the use of coils and other devices for occlusion, removal of embolised foreign bodies in the central and peripheral circulation is not infrequently performed in the catheterisation laboratory. Most of the foreign bodies and devices are radio-opaque in parts, if not in their entirety, and can be easily identified on radiography. Various devices based on those used in urological practice have been

used for retrieval. Depending upon the location of the foreign body to be retrieved, access is achieved in arterial or venous circulation. Usually, two routes are used for access, one with the device, and the other for multiple angiograms to assess proximity to the foreign body.

Snares are the most versatile and commonly used devices. They function like a lasso, encircling and tightening around the object to be retrieved. The snare is delivered through a large sheath to reach the foreign body. Once snared, the foreign body is pulled into the sheath, and removed from the circulation.

Basket devices were designed for removal of biliary and renal stones. They are made of multiple wires arranged to protrude in different directions, and then converge to form a basket which can hold devices. They can be used to retrieve larger foreign bodies that can be compressed, and may need larger bore sheaths. Forceps, either specifically designed for retrieval or those used for endomyocardial biopsy, have also been used.¹¹⁹ The risk of vascular trauma during retrieval should be borne in mind and surgical removal of a foreign body considered if interventional techniques fail.

INTERVENTIONS ON SURGICAL AND OTHER NATURALLY OCCURRING ABNORMAL PATHWAYS

Coils and devices made of Nitinol have been used to occlude other structures with abnormal vascular communications, including systemic or pulmonary arterio-venous fistulas, veno-venous (Fig. 17-27) or veno-arterial communications,¹²⁰ aorto-pulmonary shunts, and systemic-to-pulmonary collateral arteries (Fig. 17-28).^{121,122} Closure of surgically created fenestrations in the Fontan circulation can be successfully performed with a wide variety of devices. The Amplatz atrial septal occluder (Fig. 17-29) and Helex (Fig. 17-30) are the most commonly used.^{123,124} A careful haemodynamic assessment should be performed before occluding the fenestration. A test occlusion of the fenestration with a balloon catheter, with a subsequent rise in systemic arterial saturations, should be performed. Measurement of systemic venous saturations to assess the arterio-venous oxygen difference serves as a surrogate for the cardiac output. An increase of more than 16 mm Hg, a significant decrease in the cardiac output after test occlusion of the fenestration, or presence of protein losing enteropathy, are contraindications to closure of fenestration.

Conduits of different types are commonly used to repair complex congenital cardiac disease. Biological valved conduits

Figure 17-27 Occlusion of a systemic-to-pulmonary venous collateral vessel in the Fontan circulation to reduce systemic arterial de-saturation.

or tubes have been used to establish continuity between the right ventricle and pulmonary arteries during both definitive repairs and palliative surgery. Obstruction of the conduit may result from external anatomical constraints, twists and folds within the tubes, or degeneration with calcification. Balloon dilation usually provides only transient relief of obstruction¹²⁵ and implantation of stents is commonly used to palliate or prolong the life of the conduit,¹²⁶ especially after calcification and obstruction resulting in right ventricular hypertension. Coronary arterial stents have been used to improve flow of blood to the lungs after Norwood palliation for hypoplastic left heart syndrome. Interventional procedures on systemic-to-pulmonary conduits providing obligatory pulmonary blood flow have a high risk of morbidity and mortality. Obstructions to anastomosis of conduits involving the pulmonary bifurcation are also difficult to treat.¹²⁷

Steps involved in stenting of conduits include assessment of the size of the conduit, selection of the balloon and stent, use of stiff exchange-length guide-wires to provide strong support to the long sheaths used to deliver the stents,

Figure 17-28 Occlusion of a systemic-to-pulmonary collateral artery from the descending aorta with an Amplatz duct occluder.

Figure 17-29 Closure of a Fontan fenestration and a baffle leak using Amplatz atrial septal occluders.

and the use of high-pressure balloons for rigid conduits. The advent of balloon-in-balloon catheters has facilitated positioning of the stents. High-pressure balloons requiring 10 to 12 atmospheres, with the use of indeflators, are effective in dilating rigid calcified homografts. Pre-dilation

Figure 17-30 A Helix device is inserted in an intracardiac conduit providing a total cavopulmonary connection, completely occluding a fenestration.

of the conduit may be necessary in the setting of tight stenosis to facilitate delivery of the long sheath beyond the site of implantation.

Complications include embolisation, dissection, or rupture of conduits with bleeding, coronary arterial compression with myocardial ischaemia or tricuspid regurgitation.¹²⁸ Free pulmonary regurgitation is an expected consequence of dilating conduits placed from the right ventricle to the pulmonary arteries, which may prove deleterious in the long-term. Insertion of valved stents may help avoid this complication in the future.

HYBRID PROCEDURES: COLLABORATION BETWEEN THE SURGEON AND THE INTERVENTIONIST

Treatment of complex congenital cardiac diseases has traditionally required close collaboration between the cardiologists and cardiac surgeons. A new relationship between the interventional cardiologist and the cardiac surgeon has led to the development of combined transcatheter and surgical therapeutic options, now called the hybrid approach. This involves complementary interventions by the interventional cardiologist and the cardiac surgeon. The principle of this approach came from treatment of hypoplastic left heart syndrome, stenting the arterial duct and performing balloon atrial septostomy or surgical septectomy, combined with bilateral banding of the pulmonary arteries to provide initial short-term palliation.¹²⁹ This hybrid approach has now been used in a systematic and reproducible manner for patients with hypoplastic left heart syndrome,¹³⁰ and the technique extended to develop truly hybrid suites in which both the interventional cardiologist and surgeons can operate together¹³¹ (Figs. 17-31 and 17-32). A similar combined approach has been applied in closure of muscular ventricular defects.¹³² The closure of single or multiple defects in the apical part of the

muscular septum, which are difficult to reach through the tricuspid valve, or require a ventriculotomy, may be closed using the periventricular approach or with intra-operative interventional closure using the Amplatzer muscular septal occluder. Echocardiography is extremely important to guide the operator in identifying the defects and deploying the device. The periventricular closure is performed after a median sternotomy and a right ventricular free wall needle puncture to insert a short sheath and guide-wire, into the left ventricle through the defect. Extreme caution needs to be exercised to prevent the dilator of the sheath perforating the posterior wall of the left ventricle. This part of the procedure, therefore, is performed under continuous echocardiographic guidance. An Amplatzer muscular septal occluder is then deployed through the sheath in the standard fashion with echocardiographic visualisation. Meticulous de-airing and flushing of the system should be carried out throughout the procedure.

Intraoperative stenting of pulmonary arterial branches has been used to rehabilitate severely hypoplastic or stenotic vessels during complex repairs.^{133–135} Insertion of the stents under direct vision is very effective in improving the size of the pulmonary arteries, and in reducing operating time. Further interventions may be necessary to redilate the stents, or provide surgical enlargement after removal of the stents during subsequent procedures.

COMPLICATIONS OF INTERVENTIONAL CATHETERISATION

Complications of cardiac catheterisation in general such as vascular injury, bleeding, arrhythmia, thromboembolism, cardiac perforation, air embolism, infection, and death could occur during interventional catheterisation. The use of large sheaths, stiff wires, large devices, and high-pressure balloon inflations all add to the standard risk.

The use of various new devices and procedures, even in the hands of experienced operators, contribute to the problems seen during the learning curve. Appropriate training, use of simulation software modules, and peer-to-peer hands-on training have made a significant contribution towards reducing these problems.

Balloons can rupture at full inflation at a high pressure, or due to disruption against a sharp edge of calcium or a previously implanted stent. Meticulous de-airing should be carried out to prevent the risk of air embolism. A circumferential tear in the balloon material leads to risk of embolisation of the material into the circulation. The ruptured balloon, when removed from the patient, should always be thoroughly examined to confirm that no residual parts have remained in the circulation. Maintaining the guide-wire position is crucial in these circumstances. A large-bore long sheath and a snare are then used to remove the remnants.

Embolisation may occur during deployment of stents due to displacement over the balloon. Usually, the stent can be fixed over a partially inflated balloon, and parked in a vessel without compromising vascular supply to any vital organs. Expanded stents within cardiac chambers may need to be removed surgically.

Dislodged devices, and embolisation, are often treated with transcatheter techniques. The basic principles of retrieval of foreign bodies from the circulation are applied. The primary aim should be to avoid haemodynamic compromise and injury to cardiac structures during retrieval, rather than avoidance of surgery. Large sheaths and a variety of devices may have to be used.

Difficult catheter manipulations lead to risk of knotting of catheters within small cardiac chambers or blood vessels. It is important to avoid this complication by careful manipulation of catheters and wires, with screening at all times during difficult procedures.

Trouble-shooting for unanticipated but well-described complications should be part of the training of an interventional cardiologist. As the incidence of complications in well-established procedures is decreasing over time due to technical advances in catheter and technology, younger interventional cardiologists are less exposed to problem-solving on their feet. Prevention of complications still remains the best way of staying out of trouble during interventional catheterisation. Surgical back-up should always be available for a cauterisation laboratory undertaking complex intervention.

Cross Sectional Echocardiographic and Doppler Imaging

LUC L. MERTENS, MICHAEL L. RIGBY, ESTELA S. HOROWITZ,
and ROBERT H. ANDERSON

Since the late 1970s, perhaps the most important change in the practice of clinical paediatric cardiology has been the introduction of cross sectional echocardiography, with this advance then being facilitated by ongoing and continuous technical improvements. Echocardiography currently allows highly accurate diagnosis of nearly all morphological abnormalities, for the most part making invasive diagnostic techniques obsolete. Nowadays, cardiac catheterisation and angiography is no longer a routine investigation in most patients prior to cardiac surgery, as it used to be a few decades ago. Indeed, the main indication for such an investigation, apart from the purposes of intervention, is the display of structures beyond echocardiographic visualisation, such as peripheral pulmonary arteries, distal coronary arteries, and more rarely complex abnormalities of systemic and pulmonary venous return. For these indications, magnetic resonance and computerised tomographic imaging are progressively replacing cardiac catheterisation. All paediatric cardiologists, cardiac intensivists, and paediatric cardiac surgeons, therefore, should be familiar with echocardiographic imaging and diagnosis. The first part of this chapter is devoted to the principles of cross sectional and Doppler echocardiography as applied in clinical practice. In the subsequent parts of the chapter, our colleagues discuss some more advanced applications, such as tissue Doppler techniques, three-dimensional echocardiography, and computed tomography and magnetic resonance imaging.

PHYSICAL PRINCIPLES OF ULTRASONIC IMAGING

We begin with a limited introduction to the physical principles of ultrasound, as some background knowledge is relevant for optimization of images in clinical practice. Those interested in more details on the physics of imaging should consult more comprehensive reviews, or specialised textbooks of echocardiography.¹

The Physical Properties of Ultrasound

An acoustic wave is a mechanical wave causing particles to be displaced from a position of equilibrium while traveling through the medium, causing local compression and rarefaction influenced by the elasticity and density of the medium. Ultrasonic waves are longitudinal sound waves with a frequency above 20 kHz, the highest frequency which can be detected by the human ear. The waves are generated and detected by a piezoelectric crystal, which deforms under the influence of an electrical field. The velocity of a sound wave is dependent upon the density

and stiffness of the medium. Stiffness is the hardness or resistance of the material to compression. Density is the concentration of the matter. Increase in stiffness also increases speed, whereas an increase in density decreases speed. Transmission of such sonic waves is slow in air or gasses, but fast in solid mediums. In the tissues of the body, the velocity of sound is relatively constant, at 1540 m/sec. The frequency represents the numbers of cycles occurring in each second of time, and is expressed in hertz, with 1 hertz corresponding to one cycle per second. The wavelength corresponds to the length over space over which one cycle occurs. The amplitude reflects the strength divided by the intensity of a soundwave, and is expressed in decibels. The velocity of transmission, the frequency, and the wavelength are related by the formula $c = f \times \lambda$, where c is the speed of sound through the medium, f is the frequency of the wave, and λ is the wavelength.

The range of frequencies used for medical applications is from 2 to 12 megahertz (MHz). Corresponding wavelengths, therefore, are in the range 0.8 to 0.13 mm. This implies an intrinsic limitation for spatial resolution, as two structures need to be separated by more than one wavelength in order to be resolved. This relationship also explains why a probe with a higher frequency has a greater spatial resolution. When sound travels through a homogeneous medium, different interactions occur, such as reflection, attenuation, refraction and scattering. Reflection occurs at a boundary or interface between two mediums having a different acoustic density. The difference in acoustic impedance, known as z , between the two tissues causes reflection of the sound wave in the direction of the transducer. Reflection from a smooth or specular interface between tissues causes the sound wave to return to the transducer. Irregular interfaces will cause scatter in different directions. The ultrasonic image is created based on the reflected waves. Refraction is the phenomenon that the ultrasound wave, which passes through the tissue, is refracted based on the incidence of the beam. The incidence is oblique when the direction of the sound beam is not at a right angle to the boundary of the two mediums. This same phenomenon explains why a straight pencil that sits in a glass of water appears to have a bend in it. Attenuation is the loss of sonic energy as sound propagates through a medium. It is produced by the absorption of the ultrasonic energy by conversion to heat, as well as by reflection and scattering. The deeper the wave travels in the body, the weaker it becomes. The amplitude and strength of the wave decreases with increasing depth. Overall attenuation is dependent upon the frequency, such that ultrasound with lower frequencies penetrates more deeply into the body

than ultrasound with higher frequencies. Probes with lower frequencies produce better penetration, but as mentioned above, have lower spatial resolution. Probes with higher frequencies have lower penetration, but higher spatial resolution. Attenuation also depends on acoustic impedance, and on mismatch in impedance between adjacent structures. Since air has a very high acoustic impedance, any air between the transducer and the cardiac structures of interest results in substantial attenuation of the signal produced. This is avoided on transthoracic examinations by use of water-soluble gel to form an airless contact between the transducer and the skin. The air-filled lungs are avoided by careful positioning of the patient, and by the use of acoustic windows that allow access of the ultrasonic beam to the cardiac structures without the need to pass through intervening lung tissue. Attenuation causes decrease in amplitude as the wave passes through the tissue. In most ultrasonic systems, this is corrected for by automatic compensation. Further manual compensation in terms of gain in depth or time can be achieved by changing controls on the machine, which correct for the automated attenuation at specific depths of image.

Production of Images

Each ultrasonic pulse, encountering numerous interfaces, gives rise to a series of reflected echoes returning at time intervals corresponding to their depths. In this way, each pulse from the ultrasonic crystal demonstrates a line of information that corresponds to the structures encountered by the sound beam. The returned signal is processed so that the radiofrequency signal is converted into an image. The M-mode represents one line of information displayed on the vertical axis, with time on the horizontal axis. Its advantage is the very high temporal resolution. The frequency of repetition of the pulse producing a typical M-mode trace is approximately 1000 frames per second. The shade of grey on the M-mode recording is determined by the intensity of each reflected echo.

Conventional cross sectional echocardiography depends on the construction of an image using multiple individual lines of information. Typically 64 or 128 lines of information are required to produce one image or frame. Multiple frames are constructed in real time each second, the limiting factor being the time necessary for the echoes from each pulse to return to the transducer. At depths of 5 to 15 centimetres, it is possible to achieve frame rates of 28 to 50 per second. Modern systems are capable of manipulating the frame rates by sending out different pulses at different times, but in general increasing the frame rate will reduce the quality of the image, and hence its spatial resolution.

Quality of Images

When concerning the image, quality refers to the resolution of the imaging system. Spatial resolution refers to the capacity of the system to resolve small structures. It can be considered as the smallest distance by which the system is capable of identifying two dots as separate entities. Contrast resolution is the ability of the system to distinguish differences in the density of the soft tissues. Temporal resolution refers to the capacity of the system

to resolve differences in time. There are many potential sources for artifacts in ultrasonic images that affect their quality.

Spatial Resolution

This can be defined as the combination of axial and lateral resolution. Axial, or depth, resolution is the capacity of the ultrasonic system to distinguish how close together two objects can be along the axis of the beam, yet still be distinguished as two separate objects. Wavelength affects axial resolution, and it is improved by increasing the frequency. Axial resolution is much higher compared to lateral resolution, which is the capacity of the system to resolve two adjacent objects that are perpendicular to the axis of the beam as separate entities. The width of the beam affects the lateral resolution: the wider the beam the lower the lateral resolution. This is influenced by the focal zone, which is the depth of the smallest beam width. The near field is the zone between the transducer and the focal zone, and the far field is the region beyond the focal zone. Optimising the focus at a certain depth optimizes lateral resolution. The limit using the focal zone is determined by the size and frequency of the transducer. Small transducers focus well in the near field, while large transducers perform better in the far field. The width of the beam is also influenced by the frequency of the transducer, with higher frequency probes having a better lateral resolution compared to those which have a low frequency. Probes with higher frequency, however, suffer from their limited ability to penetrate into the tissue. Line density can also be improved by decreasing the sector width, resulting in better lateral resolution, but more limited image sector.

Temporal Resolution

To image moving objects, structures such as blood and heart, the frame rate is important, and is related to the motion speed of the object. The eye generally can only see 25 frames per second, providing a temporal resolution of about 40 msec. The temporal resolution is limited by the sweep speed of the echo beam, which in turn is limited by the speed of sound, as the echo from the deepest part of the image has to return before the next pulse is sent out at a different angle in the neighboring beam. The speed of the sweep can be increased by reducing the number of beams, or increasing the beam width in the sector, by using the frame rate control, or by decreasing the width of the sector. The first option decreases the lateral resolution, while the second decreases the image field. Temporal resolution, therefore, cannot be increased without a trade-off, due to the physical limitations of echocardiography.

Ultrasonic Imaging Artifacts

There are many potential sources for artifacts in echocardiography. For interpretation of the images it is important to know and recognise them.

- Drop-out of parallel structures. When structures are parallel to the ultrasonic beam, there is very little reflection caused by the structure, resulting in drop-out. A typical example is the atrial septum when viewed from the apex.
- Acoustic shadowing. Transmission of the ultrasonic beam through the tissue is influenced by the presence of tissue with very high density. Typical examples are prosthetic valves, devices, catheters, or calcifications.

These structures can make it impossible to view structures behind them.

- Reverberations can occur with lateral spread of high-intensity echos. Bright echos can have considerable width. A lot of reverberations originate from the interaction between the transducer and the ribs.
- Mirror-imaging. This artifact appears as a display of two images, one real and one artifactual, and is due to the sound beam interacting with a strong reflector.
- Ring down or comet tail. The ring down artifact comes from gas bubble in a fluid medium. The comet tail originates from highly reflective structures, such as surgical clips.

Doppler Echocardiography

The Doppler principle is the frequency shift caused by ultrasonic waves if they are reflected by a moving reflector. The frequency of reflected waves increases as the target approaches the receiver, and decreases as it moves away from the observer. A typical example is the sound of an ambulance siren, which has a higher pitch sound when moving towards the observer, and a lower pitch sound when moving away. When initially applied to echocardiography, the Doppler technique was used to measure the velocities of blood pools. A Doppler shift is caused by interaction of the ultrasonic beam with a moving pool of red blood cells. The Doppler shift depends upon the velocity and direction of the flowing blood, the angle between the beam and the flow, and the velocity of sound within the tissues. This is expressed in the Doppler formula:

$$F_d = \frac{2F_0 V \cos \theta}{c}$$

where F_d is the observed shift in frequency, F_0 is the transmitted frequency, V is the velocity of flow of blood, θ is the angle of intercept between the beam and the direction of blood flow, and c is the velocity of sound in human tissue, which is 1540 m/sec.

The observed frequency shift is several kilohertz in magnitude, and produces an audible signal that can be electronically processed and displayed graphically. As different velocities are present within the ultrasonic beam for any given time instance during the cardiac cycle, a range of Doppler frequencies is typically detected. Thus, a spectrum of Doppler shifts are measured and displayed in the spectrogram, hence the term spectral Doppler as often encountered in the literature. The Doppler-shifted frequencies usually undergo fast-Fourier transformation, converting the original Doppler waveform into a spectral display with velocity on the vertical axis, time on the horizontal axis, and amplitude as shades of grey. Conventionally, Doppler signals from blood moving towards the transducer are displayed above the baseline. Similarly, when blood flows away from the transducer, the display is below the baseline. When the Doppler shift is known, the Doppler equation outlined above can be rearranged to

$$V = \frac{cF_d}{2F_0 \cos \theta}$$

In this way, the velocity of flow can be calculated. The main source of error is in the determination of the angle of intercept between the ultrasonic beam and the axis of flow. When the angle exceeds 20 degrees, it should be measured and included in the Doppler equation. In practice, it is difficult to measure accurately this angle. Potential problems arising from a large angle of interception, therefore, are overcome by obtaining the clearest audio signal with the highest velocity. The ultrasonic beam can then be assumed to be nearly parallel to the direction of flow. As blood velocities cause a Doppler shift in the audible range, the Doppler shift itself can be made audible to the user. A high pitch, with a large Doppler shift, corresponds to a high velocity, whereas a low pitch, with a small shift, corresponds to a low velocity.

Types of Doppler Ultrasound

There are three types of Doppler ultrasound, namely continuous wave, pulsed wave, and colour flow Doppler.

Continuous Wave Doppler

In continuous wave Doppler, one piezoelectric crystal is used for transmitting a continuous wave at a fixed frequency, and a second crystal is used continuously to record the reflected signals. Both crystals are embedded within the same transducer with a slight angle towards each other, and the Doppler shift is continuously sampled. As an ultrasonic wave is transmitted continuously, no spatial information is obtained. Indeed, all velocities occurring anywhere within the ultrasound beam, in other words on the selected ultrasound line of interrogation, will contribute to the reflected signal, and will appear in the spectrogram. As the ultrasound signal weakens with depth due to attenuation, velocities close to the transducer will intrinsically contribute more than the ones occurring further away. The major advantage of continuous wave Doppler is its ability accurately to measure high frequency shifts with no upper limit. It can be used, therefore, to measure high-velocity jets. To optimize the direction of the echobeam within the direction of the flow, cross sectional imaging and color Doppler can be combined with continuous wave Doppler from the same transducer, producing so-called Duplex scanning. This gives a visual impression of being simultaneous, but is achieved by rapid and automatic switching between Doppler and cross sectional imaging. Adding colour Doppler imaging helps optimally to align the beam of interrogation with the direction of the flow of blood.

Pulsed Wave Doppler

Pulsed wave Doppler has been developed to give spatial information on the detected velocities. The technique is not based on the Doppler principle, but provides an output in a spectral display which looks very similar to the way the continuous wave signal is represented. The Doppler shift itself, however, is not measured by the system. When using the pulsed wave system, an image line is chosen along which ultrasonic pulses are transmitted at a constant rate. This rate is the pulse repetition frequency. Instead of continuously sampling the backscattered waves, only one sample of the reflected wave is taken at a fixed time after transmitting a certain pulse. This time interval is the range gate. The range gate will determine the exact depth where velocities are measured. The transducer sends pulses, and must receive that signal back before other pulses can be transmitted. A sample volume is positioned at the area of interest. The velocity of sound in soft tissue is a given

constant of 1540 m/sec, and the go and return time is used to determine the depth of the sample volume.

The velocities that can be measured are limited by the pulse repetition frequency, or the number of pulses that are emitted per second. Aliasing of the Doppler signal occurs when the pulse repetition frequency is too low, and the returning signals from one waveform are not received before the next waveform is sent. The frequency at which aliasing occurs is also called the Nyquist limit. Aliasing will result in velocities being displayed at the same time below and above the baseline. The Nyquist limit will be lower the deeper the velocity is measured, as the time for the wave to travel will be longer. The Nyquist limit depends on the frequency of the probe, with higher frequency probes having lower Nyquist limits, and lower frequency probes having higher Nyquist limits. A 2.5 mHz transducer will display velocities of twice the magnitude of those produced by a 5.0 mHz transducer. Appropriate selection of the probe, therefore, is important when performing pulsed Doppler measurements. Different options are possible further to increase the Nyquist limits. The first is to shift the baseline so that velocities are measured in only one direction. A second method is to send out a new pulse before the previous one has returned. This is called the high-repetition frequency method, and results in measuring velocities in more than one site or sample volume, thus reducing the spatial resolution but increasing the Nyquist limit. The size of the sample volume can also be adjusted. A smaller sample volume will result in a sharper velocity profile, as fewer velocities are sampled at the same time.

Colour Flow Interrogation

Colour Doppler displays the direction and flow velocities of the blood superimposed on the cross sectional image. In this technology, different pulses are sent across an image line, and the phase shift between the different signals is measured at two sampling points. This phase shift is proportional to the velocity of the reflecting object. A colour is assigned to the direction of flow according to whether it is away from or towards the transducer. In this respect, it may be helpful to remember the mnemonic BART, indicating blue away and red towards.

The velocity of flow is displayed in shades of these colours. The brighter the colour, the higher is the velocity. The colour information represents the mean velocity of flow. When the flow is disturbed, or not laminar, the pattern will show as a mosaic. This mosaic pattern is only produced if the variance is on. The variance is a colour Doppler option that is present with all the cardiac presets. It is important to appreciate that, because colour flow mapping is a form of pulsed Doppler, it is subject to the same physical principles. Increasing velocities are represented as increasingly bright forms of red or blue until they reach the Nyquist limit, when aliasing then superimposes new colours on the display. Typical Nyquist velocity limits are from 0.6 to 1 m/sec. For flows at high velocity, therefore, multiple aliasing occurs. The colour image is then useful only from a qualitative point of view, and does not permit the demonstration of directional flow. Similarly to pulsed Doppler, the Nyquist limit is dependent on transducer frequency and depth.

Colour flow Doppler provides information regarding the Doppler shift from an entire area, unlike pulsed Doppler, which samples from a specific point. More time

is required, therefore, for colour Doppler to compute the lines of information onto the screen. Frame rate and line densities are reduced proportional to the time required. Keeping the colour sector small will provide a better frame rate, and produce a flicker-free image. When using colour flow, the operator is able to visualize the flow of blood in relation to the surrounding structures, which provides a method for rapid interpretation of abnormal location and direction of flow, and helps to guide Doppler interrogation of abnormal flow.

Comparison of Doppler Methods

The three types of Doppler interrogation described are complementary, each measuring the velocities of flow in different ways. For the evaluation of high velocities, the method of choice is continuous wave Doppler, since it does not give rise to aliasing. Although it does not permit gating for precise localisation of the target, a steerable cursor line, and a focused beam, allows precise alignment, thus assuring appropriate measurements of flow. Pulsed Doppler, in contrast, enables measurements of flow at a known depth, allowing more precise calculations, but is limited by the maximal measurable velocity. Colour flow Doppler is a qualitative method, but provides spatial information not obtained with other methods. By permitting visualisation of the disturbed jet, it facilitates the alignment of the continuous wave Doppler beam. The visual effect of colour flow Doppler provides a method of rapidly screening abnormal velocities within the heart, thus directing the more quantitative methods.

EQUIPMENT

M-Mode Imaging

M-mode echocardiography is derived from an M line superimposed on a cross sectional image. The M-mode trace itself shows time as the second dimension. Control of the speed of the sweep enables accurate measurements of intervals in the cardiac cycle, and the high-repetition frequency of the technique allows not only excellent temporal resolution of moving structures, but also precise measurements of mural thickness and cavity size. In this way, the information derived is superior to that obtained from cross sections. M-mode echocardiography is still commonly used for the evaluation of left ventricular function, using short- or long-axis cuts through the left ventricle, and the timing of cardiac events such as left ventricular ejection time, using a long-axis cut through the aortic valve.

Cross Sectional Imaging

Rather than mechanically moving or tilting the ultrasound crystals, as was the case with the mechanical probes from the previous generation, modern devices make use of electronics to steer the beam. For this purpose, an array of piezoelectric crystals is used. The crystals can be organized in a linear or curved fashion, or more recently in a two-dimensional matrix. By introducing delays between the excitation of different crystals in the array, the ultrasonic wave can be directed without moving the transducer. The signal for transmission in a particular direction is the sum of the signals received by the individual elements. These individual contributions can be filtered, scaled, and time-delayed separately before summing to create the image.

This process is referred to as beam-forming. In the newest generation of matrix transducers, a large number of crystals are implanted in a two-dimensional matrix, which enables full steering of the beam in all three dimensions, and is capable of generating three-dimensional images. Currently, a high-frequency matrix transducer has been developed by Philips Medical Systems, which allows high resolution three-dimensional imaging in children. The current resolution of the three-dimensional images produced, however, is significantly lower compared to the spatial and temporal resolution which can be obtained using the current probes available for cross sectional imaging.

When performing cross sectional imaging, the most appropriate probe must be selected to optimise the quality of the images produced. Probes with higher frequencies, as already discussed, have better spatial resolution but lower penetration, while probes with lower frequencies have a lower spatial resolution but higher penetration. In neonates and small infants high-frequency transducers from 7.5 to 12 MHz provide excellent cross sectional resolution. Older children, in contrast, are better studied with transducers of lower frequencies, from 5 to 3.5 MHz. Harmonic imaging was developed further to optimize the quality of the images, and to reduce the signal-to-noise ratio. Due to the phenomenon of distortion during propagation through the tissues, harmonic frequencies combining integer multiples of the transmitted frequency are generated. Transmitting a pulse of 1.7 MHz, for example, will result in the spontaneous generation of harmonic components of 3.4, 5.1, 6.8, 8.5 MHz, and so on. These harmonic components will grow stronger with the distance of propagation. The scanner can be set up in such a way as to receive only the second harmonic component, thus generating a second harmonic image. Such an image typically produces a better signal-to-noise ratio by avoiding the clutter noise due to reverberation artifacts, such as those produced by the ribs. Such harmonic imaging is often used in patients with poor acoustic windows. Its disadvantage is the reduction produced in axial resolution in the direction of the echobeam. In smaller patients, therefore, it rarely improves the quality of the images, but the technique can be useful in larger children with poor acoustic windows.

Blood-Pool Doppler

Optimising the Settings for Continuous Wave Doppler

The continuous wave image is an echocardiographic image that is influenced by all the parameters that affect a normal cross sectional picture. The gain control affects the ratio of the strength of the output signal to the input signal. The gain controls, therefore, should be manipulated to produce a clean uniform profile, without any blooming. The controls should be increased to over-emphasise the image, and then adjusted down. This will prevent any loss of information because of too little gain. The compress control assigns the varying amplitudes a certain shade of grey. If this control is either very low or very high, the quality of the spectral analysis graph will be affected, and this may lead to erroneous interpretation. The reject control eliminates the smaller amplitude signals that are below a certain threshold. This helps to provide a cleaner image, and may make measurements more obvious. The filter is used to reduce the noise that occurs from reflectors produced

from walls and other structures that are within the range of the ultrasonic beam. The volume button should be at the appropriate level to hear the frequencies.

Optimising the Settings for Pulsed Doppler

The frequency of the probe will affect the Nyquist limit of pulsed Doppler, with probes of higher frequency having a lower Nyquist limit. The gain control, compress, and filter settings are similar to those described above for continuous wave Doppler. Shift of the baseline allows the entire display to be used to show either forward or reverse flow, a feature which is useful if the flow is only in one direction. The scale should always be optimised, and be set no higher than necessary to display the measured velocities. The size of the gate should be optimised, with an increase in the sample volume increasing the strength of the signal at the expense of a lower spatial resolution. In general, the smallest sample volume providing an adequate ratio of signal-to-noise should be used. The update function allows for simultaneous duplex imaging to optimise the location of sampling relative to the cross sectional image. Simultaneous cross sectional imaging, however, reduces the temporal resolution. All pulsed-Doppler traces, therefore, should be obtained with the cross sectional image frozen.

Optimising the Settings for Colour Doppler

This involves optimising the gain settings, the scale, and the size of the sector. The gain should be adjusted until background noise is detected in the colour image, and then reducing it so that the noise just disappears. The scale should be adapted depending on the velocities of the flows measured. When looking at flows with high velocities, the scale should be adapted so the maximal Nyquist limit is chosen. When flows of low velocity are studied, such as venous flows or those in the coronary arteries, the scale needs to be lowered. The size of the colour sector needs to be adjusted to optimise frame rates. The smallest necessary size should be used.

STORAGE AND REPORTING OF THE IMAGES CREATED

All current echocardiographic machines allow the recording and storing of images in a digital format, which can be retrieved, viewed, and further analysed on a digital viewing system and work station. This allows easy storage and retrieval of echocardiographic images and studies. More and more centres use digital systems for reporting, which can be integrated within the reviewing stations. The full digital workflow contributes to the quality and efficiency of paediatric echocardiographic laboratories.^{2,3}

NORMAL CARDIAC ANATOMY

With cross sectional echocardiography, the clinician has at his or her disposal the technique to illustrate cardiac anatomy in all the detail seen by the morphologist, as described in Chapter 2. To take advantage of the material displayed, a thorough knowledge of normal and abnormal cardiac morphology is essential. It has been rare in the past, however, to find cardiac structures displayed by morphologists as they are oriented within the body. For example, the mitral valve is usually illustrated by incising the atrio-ventricular junction, and spreading the valvar leaflets and papillary muscles. This gives a spurious impression of the

Figure 18A-1 The cartoon shows the position of the cardiac silhouette relative to the thorax, and the discrepancy in angulation of the long axis of the heart relative to the long axis of the body.

disposition of the papillary muscles. In life, they are adjacent. The echocardiographic sections display the anatomy in cross section. It is helpful, therefore, if the morphologist displays the anatomy in similar fashion. Understanding is helped further by illustrating the anatomical sections in the normal orientation of the heart as it is positioned in the body.⁴ In the normal subject, the long axis of the heart is oblique, extending more or less from the left subcostal region to the right shoulder (Fig. 18A-1). The heart does not stand on its apex in St Valentine's fashion. In addition to the long axis being oblique, the cardiac chambers, particularly the ventricles, are arranged so that the morphologically right structures are anterior to their morphologically left counterparts (see Chapter 2). The left atrium is the most posterior of the cardiac chambers. Only its appendage projects to the border of the cardiac silhouette. The right ventricle lies anterior to the left ventricle. It swings across the front of the ventricular mass, reaching from the inferior and right-sided tricuspid valve to the antero-superiorly and leftwardly positioned pulmonary valve. The aortic valve is centrally located within the heart, and is related to all four chambers (Fig. 18A-2). This central position of the aortic valve, located between the tricuspid and mitral valves, is the key to the understanding of cardiac anatomy. Because of the wedged position of the aortic valve, the subaortic outflow tract lifts the leaflets of the mitral valve away from the ventricular septum. Hence, there are no direct attachments of tension apparatus to the muscular septum in the left ventricle. In contrast, the septal leaflet of the tricuspid valve hugs the septum (Fig. 18A-3), and is attached to it by tension apparatus along its length. The short-axis cuts emphasise

Figure 18A-2 The cartoon shows the position of the cardiac valves relative to the cardiac silhouette.

Figure 18A-3 This section through the normal heart simulates the echocardiographic four-chamber section. Note that the septal leaflet of the tricuspid valve hugs the septum, whereas there is a discrete plane of space between the septum and the leaflets of the mitral valve. The rightward border of this space is formed by the membranous part of the septum (red double-headed arrow) and the area of the atrioventricular muscular sandwich, which occupies the space between the offset leaflets of the atrioventricular valves (open arrows).

other significant differences between the right and left sides of the normal heart. The arterial and atrioventricular valves in the right ventricle are separated by the supraventricular crest. No such muscular crest exists in the roof of the left ventricle, where the leaflets of the aortic and mitral valves

Figure 18A-4 This short-axis section of the ventricular mass is viewed from the apex looking towards the base. Note the deeply wedged position of the aortic valve between the mitral valve and the septum, with fibrous continuity between the valvar leaflets in the roof of the ventricle. In contrast, the supraventricular (SV) crest forms the roof of the right ventricle, interposing between the leaflets of the tricuspid and pulmonary valves.

Figure 18A-5 This short-axis section is taken closer to the base than the one shown in Figure 18A-4. It shows the epicardial fat interposing between the wall of the right atrium and the crest of the ventricular septum at the anatomic crux. The echocardiographic crux is seen in so-called four-chamber planes, as shown by the yellow line.

are in fibrous continuity (Fig. 18A-4). The subaortic outflow tract also has important relationships to the areas of atrioventricular contiguity, these being made up of two components. The first, the atrioventricular membranous septum, is made of fibrous tissue, and is an integral part of the central fibrous body. It interposes between the medial wall of the subaortic outflow tract and the right atrium. The other area is the region of overlapping of the atrial and ventricular musculatures. It exists because the septal leaflet of the tricuspid valve is attached to the septum more towards the ventricular apex than are the leaflets of the mitral valve, producing the characteristic off-setting of the valvar leaflets. In the area between these valvar attachments, the walls of

Figure 18A-6 The image shows the location of the echocardiographic windows that permit visualisation of cardiac anatomy.

the right atrium overlap the base of the ventricular mass, thus forming a muscular atrioventricular sandwich (Fig. 18A-5). The anatomist describes the location of this area as seen from the diaphragmatic surface of the heart as the cardiac crux, representing the position where the plane of the normal septal structures crosses the inferior atrioventricular groove. The echocardiographer cannot see this point on the epicardial surface of the heart, but is able to identify the so-called echocardiographic crux, the asymmetric cruciate appearance representing the off-set attachment of the atrioventricular valvar leaflets.

Anatomical Principles of Echocardiography

All of the morphological features described above are potentially amenable to dissection with the ultrasonic beam. The echocardiographic tyro will immediately become aware that the ultrasonic beam is obstructed both by bony structures and the air-filled lungs. Because of this, access from the body surface can be limited, although the heart can be viewed from many different aspects. Unobstructed views can be obtained from the cardiac apex, from alongside the sternum through the intercostal spaces, from beneath the rib cage, and from the suprasternal notch (see Fig. 18A-6). The cardiac components can also be visualised by placing a transducer within the oesophagus and stomach. From these various windows, the heart and great vessels, according to their position within the chest, can be cut in different planes. Standard echocardiographic views are well established for patients with normally located hearts. Visualisation and understanding of the congenitally malformed heart, however, is facilitated if the examiner develops

Figure 18A-7 The heart can also be described in terms of its orthogonal planes, albeit that these are skewed relative to the long-axis planes of the body. The image shows the long-axis planes that cut through two chambers of the heart, along with the short-axis planes. The third series of planes, in the long axis, are in the plane of the image itself. They produce the so-called four-chamber cuts, as seen in Figure 18A-3.

a technique of orientation and identification based on points of reference that are internal to the heart and great vessels. For example, the sections obtained from the so-called standard approaches will be of little value when a heart is in the right chest, even though it may be structurally normal. The key to a system of universal value is to assess the heart, whatever its position, in terms of its three orthogonal planes. These planes can be described as being coronal, sagittal, and transverse relative to the heart, but the axis of the heart rarely corresponds to the axis of the body (see Fig. 18A-1). Of these cardiac orthogonal planes, two are in the long axis of the heart itself, the other being in the cardiac short axis (Fig. 18A-7). Using cross sectional imaging, these index planes cannot all be obtained from a single echocardiographic window. Simple geometric principles dictate that, from any given window, it is possible to obtain only two of these basic planes, although intermediate cuts can be taken towards the third plane.

In the simplest terms, scanning from the apical window provides the two cardiac long-axis planes. The long-axis coronal plane is at right angles to the inlet part of the ventricular septum, and is conventionally termed the four-chamber plane (see Fig. 18A-3). This is the plane that shows the anatomy of the atrioventricular contiguities. When taken through the membranous atrioventricular septum, the section also incorporates part of the subaortic outflow tract. Hence, most of these cuts show more than the four basic cardiac chambers. The designation as a four-chamber plane, nonetheless, is a useful one. The long-axis plane at right angles to the outlet part of the septum can, by analogy to the four-chamber plane, be considered as a two-chamber plane. In most cases it also included part of the right ventricular infundibulum, and illustrates more than the two basic chambers. The long-axis plane basically showing two chambers is also one of the standard planes obtained from the parasternal window (Fig. 18A-8), together with the series of short-axis planes (Fig. 18A-9). When scanning from subcostal and suprasternal windows, it is no longer

Figure 18A-8 This section simulated the parasternal long-axis echocardiographic cut. Note that, in addition to showing the left atrium and ventricle, it also shows the infundibulum of the right ventricle.

Figure 18A-9 This short-axis section through the ventricular mass simulating the echocardiographic parasternal short-axis cut shows the curved arrangement of the ventricular septum and the oblique orientation of the left ventricular papillary muscles. Note that, when the heart is positioned as it lies in the chest during life, these muscles are positioned infero-anteriorly and supero-posteriorly.

possible to cut a normally positioned heart in its own axes, although this may be possible when the heart is abnormally positioned. Instead, the usually located heart is cut in paracoronal and parasagittal planes relative to the axes of the body. From subcostal position, such cuts produce sections that are similar to, but differ subtly from, the four-chamber and short-axis planes. For example, a paracoronal cut can, on occasion, replicate a heart with absence of the right atrioventricular connection, even when two normal atrioventricular valves are present. These cuts also show to advantage the location of the membranous septum, and how the inferior part of the muscular ventricular septum separates the right ventricular inlet from the outlet of the left ventricle (Fig. 18A-10). These cuts also show the long axis of the aortic arch, although this is probably better seen from the suprasternal window. Many views must be used to obtain a complete impression of cardiac structures. Despite the need for presentation and description of echocardiographic findings in terms of cuts, the key to successful evaluation is to obtain continuous scans from one view

Figure 18A-10 When scanning from the subcostal position, as shown by the arrow, the transducer beam moves more in the planes of the body than in the planes of the heart. Thus, a series of paracoronal cuts of the heart are obtained, as shown in the inset. Rotating the transducer through 90 degrees will produce a series of parasagittal cuts.

to another. In practice, the echocardiographer builds up a three-dimensional whole from a series of two-dimensional parts. The experienced investigator will use any view, no matter how unorthodox, to attain this objective.

Transthoracic Echocardiography

A full echocardiographic study involves a complete description of cardiac anatomy, valvar function, and cardiac systolic and diastolic function. Transthoracic windows are excellent in the majority of infants and children, so that interrogation from these windows can provide all anatomical, haemodynamic, and functional information required for diagnosis and treatment of most of the congenital and acquired cardiac lesions encountered by the paediatric echocardiographer. The majority of children are currently referred for cardiac surgery based only on transthoracic echocardiographic studies. For those aged between 3 months and 3 years, however, lack of co-operation can be a limiting factor, and sedation is generally required to permit performance of an adequate echocardiographic study. Transoesophageal imaging in children is mostly limited to peri-operative imaging.

The description of cardiac anatomy is best accomplished by using the segmental anatomical approach. By combining different echocardiographic windows, it is possible to recognise the precise anatomy of each cardiac segment, along with their interconnections and relations. In this chapter, we concentrate on normal findings. The echocardiographic images of congenitally malformed hearts are described in other chapters. A detailed discussion of

functional echocardiography is beyond our present scope, so we will focus mainly on the description of cardiac anatomy, albeit discussing valvar function.

When starting a full cross sectional study in a new patient, most echocardiographers will prefer to start with subcostal imaging, as this allows inferential determination of the arrangement of the organs. The study then proceeds with obtaining parasternal long-axis, short-axis, apical and suprasternal views. A study performed for the purposes of follow-up will often start with parasternal long-axis views, deferring the subcostal imaging until the end of the examination. To help the echocardiographer to reconstruct the three-dimensional anatomy, two-dimensional sweeps can be recorded using the different cuts. For instance, a subcostal coronal sweep from posterior to anterior provides extra information in the third dimension. All images should be presented in their correct spatial, or attitudinally appropriate, position on the screen. The anterior and superior structures, therefore, are displayed at the top of the screen, and the rightward structures are generally placed on the left side of the display, with the exception of the parasternal long-axis cut when, by convention, the cardiac apex is displayed on the left of the screen. The standard views required for a paediatric echocardiographic study, as defined by the American Society of Echocardiography, are all obtained as part of a routine examination.⁵ These are the subcostal, apical, parasternal, suprasternal notch and right parasternal cuts.

Subcostal Views

Different subcostal views can be obtained. Typical cuts are obtained in a coronal plane, giving long-axis views, in the sagittal plane producing short-axis cuts, and in the transverse plane. Subcostal imaging begins with a transverse section to determine the arrangement of the abdominal organs by inference from the location of the abdominal aorta and inferior caval vein relative to the spine (Fig. 18A-11).⁶ The abdominal vessels can also be imaged in a long-axis view by rotating the probe 90 degrees counter-clockwise. Colour imaging will help to distinguish the

Figure 18A-11 Subcostal transverse cut at the level of the abdominal vessels. The inferior caval vein (ICV) is seen to the right of the spine and the aorta (AO) is seen to the left of the spine. This suggests that atrial arrangement is normal with the right atrium on the right and the left atrium on the left.

Figure 18A-12 The image shows a heart sectioned to simulate a posterior paracoronal cut obtained from the subcostal window to look at the atrial septum. The left atrium (LA) and right atrium (RA) can well be visualized. On this more posterior cut, only the left ventricle (LV) is visualized, as the right ventricle is located more anteriorly.

identity of the abdominal great vessels. Posterior coronal long-axis sections, with the transducer directed to the left of the midline, provide excellent views of the atrial septum (Fig. 18A-12). As the transducer is tilted anteriorly, the superior caval vein, the ventricles, and the left ventricular outflow tract can be imaged (Fig. 18A-13). Further anterior tilting of the probe provides views of the right ventricular outflow tract. Counter-clockwise rotation of the transducer, with the notch in the transducer positioned inferiorly at 6 o'clock, will produce different cuts as the transducer is swept from right to left in a parasagittal plane. A cut through the atriums allows imaging of the superior and inferior caval veins and the atrial septum (Fig. 18A-14). As the transducer is moved towards the left, the subcostal short-axis section of the left ventricle and the right ventricular outflow tract can be imaged (Figs. 18A-15 and 16). In this view, the right ventricular apex and outflow tract are seen, together with the pulmonary valve and proximal pulmonary trunk (see Fig. 18A-15). By tilting the transducer further to the left, the midapical and apical portions of both ventricles can

Figure 18A-13 This subcostal coronal view is tilted more anteriorly compared to Figure 18A-12. More of the right ventricle (RV) can be seen, as well as the left ventricle (LV) and the left ventricular outflow tract. The arrow points at the insertion of the aortic valve. Ao, aorta; RA, right atrium.

be imaged, along with the corresponding portions of the ventricular septum.

Parasternal and Apical Views

Parasternal imaging starts with obtaining a left parasternal long-axis view. This reference section shows the left ventricular outflow tract, the aortic valve, the mitral valve, the left ventricle and the left atrium (Fig. 18A-17). The fibrous continuity typically present between the leaflets of the mitral and aortic valves is easily demonstrated, and this view is useful for assessing mitral and aortic valvar motion and function. When the transducer is tilted towards the right hip, the right ventricular inflow and the tricuspid valve can be visualised (Fig. 18A-18). The orifice of the coronary

Figure 18A-14 The subcostal coronal view of the right atrium demonstrates the entrances of the superior caval vein (SCV) and the inferior caval vein (ICV) to the right atrium (RA). The tricuspid valve can be seen on this image, as well as part of the right ventricle (RV). On the colour Doppler figure on the right, the flow from the superior caval vein comes towards the probe, and is shown in red, while flow from the inferior caval vein is directed away from the probe, and is seen as blue.

Figure 18A-15 This subcostal short-axis cut is taken at the level of the right ventricular outflow tract. Both the right ventricle (RV) and left ventricle (LV) are shown. The right ventricular outflow tract is visualized, as well as the pulmonary trunk (PA).

Figure 18A-16 This subcostal short-axis section, tilting more leftward showing the left ventricle (LV), shows the left ventricular outflow tract and the ascending aorta (Ao). The aortic valve is shown in a closed position. The right ventricle (RV) and the ventricular septum are also seen.

sinus can also be identified in this view. With anterior tilting of the transducer, the right ventricular outflow tract, the pulmonary valve and the pulmonary trunk can be visualised (Fig. 18A-19). When the transducer is rotated 90 degrees clockwise from the long-axis reference cut, a parasternal short-axis view of the base of the heart is obtained. This view can provide information on the structure of the aortic valvar leaflets (Fig. 18A-20), the right ventricular outflow tract, and the pulmonary valve (Fig. 18A-21). A short-axis sweep is then usually performed from base to apex, which visualises the ventricular septum. Short-axis cuts are obtained at the level of the leaflets of the mitral valve (Fig. 18A-22), the papillary muscles, and the left ventricular apex. The short-axis views show well the papillary

Figure 18A-17 This parasternal long-axis view shows the left atrium (LA), left ventricle (LV) and aorta (AO). Note the fibrous continuity between the leaflets of the mitral and aortic valves. The infundibulum of the right ventricle (RV) is seen antero-superiorly.

Figure 18A-18 This parasternal long-axis view shows the right ventricular inlet. The probe is tilted so that the right atrium (RA), tricuspid valve, and right ventricle (RV) are all visualised. The left ventricle (LV) is posterior to the RV.

muscles supporting the tendinous cords of the mitral valve (Fig. 18A-23). Although conventionally described as being postero-septal and antero-lateral, examination of short-axis sections when the heart is positioned as it lies in the body reveals that these muscles are positioned infero-anteriorly and supero-posteriorly. The short-axis views also show the origins of coronary arteries. Slight clockwise rotation from the cut showing the short axis of the aorta will demonstrate the origin of the left coronary artery, while slight counter-clockwise rotation will demonstrate the origin of the right coronary artery. The arterial duct, if patent, can be demonstrated by using a high left parasternal window

Figure 18A-19 The parasternal long-axis view shows the right ventricular outflow tract (RVOT), and is obtained by tilting the probe anteriorly. The left ventricle (LV), the infundibulum, the pulmonary valve and the pulmonary trunk (PA) are all seen in this image.

Figure 18A-21 This parasternal short-axis cut of the right ventricular outflow tract (RVOT) shows the pulmonary valve, the pulmonary trunk (PA), and the right and left pulmonary arteries (LPA, RPA). AO, aorta.

Figure 18A-20 This image shows the parasternal short-axis view of the aortic valve. Three leaflets can be seen, which are supported by left coronary (LCC), right coronary (RCC), and non-coronary (NCC) aortic sinuses.

with the notch of the transducer at 12 o'clock. From the apical window, the apical four-chamber, three-chamber long-axis, and two-chamber views can be obtained. The apical four-chamber view allows interrogation of the atrioventricular valves and the morphology of the ventricular apical components (Fig. 18A-24). This view is particularly valuable for assessing apical displacement of the hinges of the leaflets of the tricuspid valve, as well as the septal insertions of the tendinous cords supporting the septal leaflet. Posterior tilting from the apical four-chamber view shows

Figure 18A-22 The parasternal short-axis section of the left ventricle (LV) shows the mitral valve (MV), with its aortic and mural leaflets. The right ventricle (RV) is anterior to the left ventricle.

the coronary sinus extending through the inferior left atrioventricular groove. Antero-superior tilting provides the apical five-chamber view, which contains the left ventricular outflow tract, the aortic valve, and the ascending aorta (Fig. 18A-25). The apical long-axis view is obtained by a 60-degree counter-clockwise rotation from the cut showing the apical four-chamber view (Fig. 18A-26). This allows visualization of the left ventricular outflow tract, as well as the

Figure 18A-23 The parasternal short-axis section of the left ventricle shows the two papillary muscles supporting the mitral valve. Note the obliquity of the papillary muscles, with the inferior muscle adjacent to the septum but anterior to its superior counterpart.

Figure 18A-25 Apical five-chamber view. Anterior tilting from the apical four-chamber view reveals the left ventricular outflow tract. In this image, the left atrium (LA), left ventricle (LV), aorta (AO), right atrium (RA) and right ventricle (RV) can all be seen.

Figure 18A-24 Apical four-chamber view. On this image the right atrium (RA) and right ventricle (RV), together with the left atrium (LA) and left ventricle (LV), can be seen. Note the slight apical displacement of the tricuspid valve relative to the mitral valve on this image.

mitral valve. The two-chamber view is obtained by further counter-clockwise rotation, and provides images of the walls necessary for assessment of left ventricular function (Fig. 18A-27).

Views from the Suprasternal Notch

When the transducer is positioned in the suprasternal notch, with the notch of the transducer itself at 3 o'clock, the standard short-axis section will demonstrate the left

Figure 18A-26 In the apical three-chamber view, it is possible to see the left atrium (LA), left ventricle (LV) and aorta (AO).

brachiocephalic vein, the short-axis cut of the aortic arch, the right pulmonary artery, and the left atrium (Fig. 18A-28). The four pulmonary veins can be seen entering the left atrium when the transducer is tilted more posteriorly, producing the so-called crab view. The right superior caval

Figure 18A-27 The apical two-chamber view shows the left atrium (LA) and the left ventricle (LV), cutting the superior and inferior walls of the left ventricle. This image is important for the assessment of left ventricular function.

Figure 18A-28 The suprasternal short-axis view shows the superior caval vein (SCV) rightward of the aorta (AO), which is cut in its short axis. Posterior to the aorta is the right pulmonary artery (RPA), and more posterior still is the left atrium (LA). When tilted a little more posteriorly, the crab view is obtained, showing the four pulmonary veins entering the left atrium.

vein is seen to the right. A more cranial angulation of the transducer demonstrates the pattern of branching of the aorta. When the first branch of the brachiocephalic artery is directed to the right, then the aortic arch itself will be left-sided, whereas when the first branch is directed leftward, the arch will be right-sided. Should the first branch from the aortic arch not bifurcate, then an aberrant origin of the subclavian artery should be suspected. Counter-clockwise

Figure 18A-29 This suprasternal long-axis view cuts through the long axis of the aortic arch, showing both the ascending and descending parts of the aorta (Asc Ao and Desc Ao). Posterior to the aorta is the right pulmonary artery (RPA), and more posterior still is the left atrium (LA).

rotation of the transducer provides a long-axis view of the aortic arch (Fig. 18A-29), with further counter-clockwise rotation and leftward angulation demonstrating the crossing of the left pulmonary artery relative to the descending aorta. Better views of the aorta are sometimes obtained with the transducer to the right of the suprasternal notch, or when it is positioned in high parasternally.

Sequential Segmental Approach to Diagnosis

Description of cardiac anatomy, be it normal or abnormal, should start with the determination of cardiac position and atrial arrangement, and then proceed with analysis of the atrioventricular and ventriculo-arterial connections. Attention is then directed at the systemic and pulmonary venous connections, abnormalities of the atriums and atrioventricular valves, anomalies of the atrioventricular septum, abnormalities of the ventricles, and anomalies of the great arteries. Attention should also be given to extra-cardiac structures, such as the pericardium, the thymus, and other aspects of the mediastinum.

Determination of Atrial Arrangement

Determining the arrangement of the atrial appendages, these being the most constant components of the atrial chambers themselves, is the first step in the diagnosis of any patient suspected of having heart disease (see Chapter 1). Even using current high resolution echocardiographic imaging, it remains challenging to recognise directly the morphology of the right and left atrial appendages. Instead, atrial arrangement is usually inferred from echocardiographic examination of the relationship of the abdominal great vessels as seen in the subcostal transverse view.⁶ Normally the inferior caval vein is located to the right of the spine, and the aorta anterior and to the left. Demonstration of the connection of the inferior caval vein to the right atrium in the long-axis view excludes interruption of the inferior caval vein, presuming that care has been taken to ensure

that more than the hepatic veins join the right atrium. If this normal abdominal arrangement of the abdominal great vessels is confirmed, it is reasonable to infer that the atrial chambers are lateralised, with the morphologically right atrium on the same side as the inferior caval vein, and the left atrium on the left side (see Fig. 18A-11). When the atrial chambers are mirror-imaged, the inferior caval vein is left-sided, and the abdominal aorta is to the right of the spine. Almost always, the hepatic veins will all drain to the inferior caval vein, entering just proximal to its junction to the right atrium. When there is isomerism of the right atrial appendages (see Chapter 22), the aorta and inferior caval vein are almost always located on the same side of the spine, either to the right or to the left, with the vein slightly anterior. At least some of the hepatic veins join the intrahepatic caval vein in this setting, although there may be partially anomalous hepatic drainage to either of the atriums. When the left atrial appendages are isomeric, there is usually a midline aorta, with a closely associated azygos vein located posterolateral to the aorta. Parasagittal sections will demonstrate that this posterolateral azygos vein does not connect with either atrium, but instead courses posteriorly to the right or left in the chest to join a superior caval vein. In left isomerism, the hepatic veins tend to drain directly to one or both of the atriums, but there can be a suprahepatic inferior caval vein, with or without anomalous hepatic venous drainage (see Chapter 22). The recognition of venous connections, however, is no more than an inferential guide to the presence of isomerism. It is much better, if possible, to identify directly the structure of the appendages.

Analysis of the Atrioventricular Junctions

The connections of atriums and ventricles across the atrioventricular junctions are determined by obtaining subcostal, parasternal, and apical four-chamber sections, as discussed above. For hearts with biventricular atrioventricular connections (see Chapter 1), the tricuspid valve, which forms an integral part of the morphologically right ventricle, typically has multiple cordal attachments to the ventricular septum. This feature is best demonstrated by the subcostal four-chamber section. In contrast, the tendinous cords from the mitral valve normally attach to two discrete left ventricular papillary muscles, and exceedingly rarely directly to the ventricular septum. In the majority of hearts with biventricular atrioventricular connections, the cordal attachments are the most reliable guide to ventricular morphology. There are, of course, other ways of determining atrioventricular valvar and ventricular morphology. In the normal heart, the medial attachments of the tricuspid valve to the ventricular septum are nearer to the ventricular apex than the corresponding leaflet of the mitral valve (see Fig. 18A-24). This is evident in any four-chamber echocardiogram, but is most striking in the apical views. There are then still other methods of identifying ventricular morphology. A parasternal short-axis section of the left ventricle will reveal the normal bifoliate mitral valve with its obliquely positioned papillary muscles. The trabecular pattern of the ventricle will appear smooth when compared with that of the right. The other characteristics of the morphologically right ventricle are the presence of a septomarginal trabeculation seen just anterior to the ventricular septum on parasternal and apical long-axis sections, an apical moderator band, best seen with parasternal four-chamber views, and

a trifoliate atrioventricular valve, best identified using the subcostal short-axis section.

Having determined the structure of the junctions, it is then necessary to establish the morphology of the valves that guard them. Cross sectional echocardiography is unique in its ability to demonstrate abnormalities of the atrioventricular valves, especially in the four-chamber sections. When both atriums connect to the ventricular mass, the atrioventricular junctions may be guarded by two patent valves, by one patent and one imperforate valve, by a common valve, or by straddling or overriding valves. These different modes of atrioventricular connection can be found with concordant, discordant, biventricular and mixed, or double inlet types of connection (see Chapter 1). Overriding and straddling are distinguished by considering the junction for the former, and the tension apparatus for the latter. When there is a common valve, it is usual to find both overriding and straddling, but this is not always the case, since the common valve can guard both junctions when they connect to the same ventricle. When one atrioventricular connection is absent, of necessity there are fewer options for the modes of connection, since there is but one atrioventricular valve. This valve is usually totally committed to one ventricle, but straddling and overriding are sometimes encountered. This produces the rare findings of a uniaxial but biventricular connection. The degree of overriding of a valve will determine the categorisation of atrioventricular connections, cross sectional echocardiography readily permitting the distinction between the biventricular and univentricular arrangements.

Analysis of the Ventriculo-arterial Junctions

When assessing the junctions between the ventricles and the arterial trunks, it is necessary first to identify ventricular morphology, using the methods already described, and then to establish the arrangement of the arterial trunks. In infants and small children, the latter information is usually derived from subcostal coronal sweeps. This is generally supplemented by other echocardiographic sections, like the high parasternal short- and long-axis views. The aorta is characterised by identifying the origin of the brachiocephalic arteries from the arch. The pulmonary trunk is recognised on the basis of its bifurcation into right and left branches. A common arterial trunk is a solitary arterial trunk giving rise in its ascending part to the coronary and pulmonary arteries and the ascending aorta. Having established the connections across the ventriculo-arterial junctions, it is also important separately to determine the arrangement of the arterial valves, the relationship between the arterial trunks, and the infundibular morphology. These features are all independent of one another, and independent of the ventriculo-arterial connections. Establishing each feature separately, and describing them all, removes the potential for ambiguity (see Chapter 1).

Paediatric Transoesophageal Echocardiography

Transoesophageal echocardiography is complementary to transthoracic echocardiography in the diagnosis and monitoring of infants and children with congenitally malformed hearts. Miniaturisation of the transoesophageal probes has allowed this technique to be applied to children weighing from around 3 to 3.5 kg. Guidelines for its use have recently been updated by the American Society of

Echocardiography.⁷ The technique has an important role in documenting the adequacy of surgical repair immediately after the discontinuation of bypass, and in the early post-operative period in the intensive care unit where transthoracic windows can be limited. In most centres, peri-operative transoesophageal imaging is performed during nearly every surgical intervention, and has been shown to have an important impact on the surgical results. Transoesophageal imaging is also indicated for monitoring various procedures used during interventional catheterisation. It can also be indicated for patients with inadequate transthoracic windows, although alternative imaging techniques like cardiac magnetic imaging are usually preferred in children.

Transoesophageal examinations are performed using systems offering cross sectional imaging, colour Doppler, continuous wave, and pulsed wave Doppler, as well as tissue Doppler. Multi-plane transoesophageal probes are currently available for use in children weighing from 3 to 20 kg. In smaller infants, this probe needs to be used with extreme caution. Epicardial imaging might still be a good alternative in this setting. The larger multi-planar probes designed for use in adults can be used in patients weighing more than 15 to 20 kg. Recently, an adult-sized three-dimensional transesophageal probe, which is about 2 mm thicker compared to the adult multi-planar probe, has become available, allowing real-time three-dimensional transoesophageal imaging. This probe can only be used in children above 15 kg, but it is expected to be miniaturised for future use in children. The probes should always pass easily without significant resistance. Complications are rare, but include oesophageal perforation, along with compression of vessels and airways. Because of these rare complications, nonetheless, continuous monitoring of the haemodynamic and respiratory state is always required. Transoesophageal echocardiography, therefore, requires at least two attending physicians, one to manage the airway and monitor the patient, and the other to perform the examination. For most infants and children, the studies are performed under general anaesthesia, using tracheal intubation under the supervision of an anaesthesiologist. For examination of intubated patients in the intensive care unit, and for study of adolescents, sedation is usually sufficient. Deep sedation may be adequate in an outpatient setting.

The absolute contra-indications to a transoesophageal examination are the presence of any pharyngeal or oesophageal lesion predisposing to laceration or perforation during manipulation of the probe. In addition, some patients with tracheomalacia may manifest a fall in systemic arterial saturation when the probe is manipulated because of tracheal compression. Although bacteraemia has been reported, the need for prophylaxis against bacterial endocarditis remains controversial. In the most recent published guidelines, the risk for bacterial endocarditis due to patients undergoing a gastrointestinal procedure was judged to be exceedingly small, not justifying the prophylactic use of antibiotics.⁸

Technique of Examination

After induction of general anaesthesia and endotracheal intubation, or following appropriate sedation, the head of the patient is positioned in the midline, or slightly to the left, the mouth opened with the jaw thrust forward, and the neck slightly extended. The unlocked tip of the probe is lubricated with a water-soluble gel, gently introduced

into the hypopharynx, and advanced until an image of the heart is displayed on the screen. If there is resistance to passage of the transducer, a laryngoscope can be used to permit introduction under direct vision. Once the transducer is appropriately positioned, the head of the patient can be maintained in the midline, or placed to face the echocardiographer. The probe is then manipulated to obtain a range of transoesophageal images. A series of transgastric sections can be obtained by manipulating the tip of the probe when it has been advanced into the stomach. In contrast to transthoracic echocardiography, there is less flexibility in the imaging planes. Multiplanar imaging allows rotation of the imaging plane between 0 and 180 degrees. Zero corresponds to a transverse view, while 90 degrees corresponds to a more longitudinal view. Use of specific angles to obtain certain images is not very useful, as the morphology might differ between individuals. The American Society of Echocardiography has issued guidelines for orientation of images, which can be used as a reference. For those with complexly malformed hearts, unusual imaging planes might be required. Some of the standard images are further discussed.

Transoesophageal Views

Midoesophageal Four-chamber View

In a transverse plane, at around zero, it is possible to produce a four-chamber view, imaging the atrioventricular valves, the ventricles, and the atrial and ventricular septums (Fig. 18A-30). The images produced are shown with the apex down, and with the left ventricle to the right of the screen. When slightly moving the probe upwards, the atrial septum can nicely be visualised. Slight rotation to the left at atrial level allows visualisation of the left pulmonary veins, and slight rightward rotation reveals the right pulmonary veins. Adding colour Doppler with a low Nyquist limit might help to identify the pulmonary veins from this view. By very slight upward and downward motion, it is possible

Figure 18A-30 This transoesophageal four-chamber view is obtained from a mid-oesophageal position. The left atrium (LA), left ventricle (LV), right atrium (RA) and right ventricle (RV) are all imaged in this projection.

to distinguish the upper and lower left and right pulmonary veins. The apical four-chamber view is well suited to the assessment of atrioventricular valvar function. Using color Doppler and pulsed wave Doppler, which generally can be well-aligned from this plane, it is possible to evaluate atrioventricular valvar regurgitation as well as stenosis. This view is also suited to assess the ventricular septum. A search is often made for residual ventricular septal defects using this particular imaging plane after discontinuation of cardiopulmonary bypass.

Midoesophageal Short- and Long-axis Views

From the mid-oesophageal position, different short- and long-axis views can be obtained. By slightly advancing and flexing the probe from a standard four-chamber view, a short-axis view at the level of the atrioventricular valves can be obtained (Fig. 18A-31). This is useful for assessing the leaflets after repair of an atrioventricular septal defect. In most patients, however, the transgastric short-axis cuts are easier to obtain, and are the ones most commonly used.

From a standard apical four-chamber view, rotating the probe to between 0 and 60 degrees with slight flexion and pull-back produces an image of the aortic valvar leaflets in their short axis (Fig. 18A-32). This usually permits the distinction of trifoliate from bifoliate valves. The origins of the coronary arteries can also be assessed from this view. The left coronary artery normally originates from the left coronary aortic sinus, while the right artery originates more anteriorly from the right coronary aortic sinus. The proximal course of the coronary arteries can generally be identified. Here, it can be extremely useful to use colour Doppler with a low Nyquist limit, thus confirming normal flow in the arteries. The same view permits identification of the membranous part of the ventricular septum, and residual ventricular septal defects if present. The antero-superior and septal leaflets of the tricuspid valves can be imaged. It is often possible to obtain good alignment with a regurgitant jet across the tricuspid valve to estimate right ventricular pressures. From the same plane, the right ventricular outflow tract, the pulmonary valve, and the

Figure 18A-32 This transoesophageal short-axis view is taken at the level of the aortic valve, showing the leaflets of the aortic valve supported by their appropriate sinuses. lcc, left coronary; ncc, non-coronary sinus; PA, pulmonary trunk; rcc, right coronary sinus; RV, right ventricle.

pulmonary trunk, can all be viewed (Fig. 18A-33). By pulling back the probe slightly, the proximal part of the right pulmonary artery, and its segment running behind the aorta, can usually be well imaged (Fig. 18A-34). Imaging the left pulmonary artery from the oesophagus can be very challenging because of the loss of the image due to interference by air as it crosses the bronchus. Slight leftward rotation might permit visualisation of the most proximal part of the artery, but this is lost as it crosses the bronchus. The distal parts can be visualised from a mid-oesophageal long-axis view, rotating the probe posteriorly to image both the descending aorta and the crossing left pulmonary artery.

When the probe is pulled back further, using the angulation between 30 and 60 degrees, a short-axis image of

Figure 18A-31 The transoesophageal short-axis view at the level of the mitral valve shows both the left and right ventricles (LV and RV). The cut provides a nice image of the mitral valve, showing the aortic and mural leaflets seen in their open position.

Figure 18A-33 This transoesophageal short-axis view shows the right ventricular outflow tract (RVOT), revealing the infundibulum, the pulmonary valve, and the pulmonary trunk (MPA). Ao, aorta; RA, right atrium; RV, right ventricle.

Figure 18A-34 This transoesophageal short-axis view shows the pulmonary trunk (MPA) and the right pulmonary artery (RPA). The proximal part of the right pulmonary artery runs posterior to the aorta (Ao). Note that the proximal left pulmonary artery cannot be seen on this view.

the atrial septum can be obtained. This image shows the antero-superior rim of the oval foramen, this being the region where most often the foramen is patent. The cut also shows the floor of the oval fossa, this being the location of true atrial septal defects. The view also proves very useful when monitoring the insertion of devices to close either a septal defect or a patent oval foramen, since it demonstrates well the relationship between the superior rim of the fossa and the device.

Rotating the probe to an angle between 90 and 120 degrees at mid-oesophageal level will produce a long-axis view of the left ventricle, this being the preferred view for imaging the left ventricular outflow tract, the aortic valve, and the supra-aortic region (Fig. 18A-35). Between 60 and 90 degrees, a two-chamber view is obtained, while a three-chamber long-axis view can be produced between 90 and 120 degrees. Addition of colour Doppler permits assessment of the left ventricular outflow tract, as well as aortic

Figure 18A-35 The colour-Doppler transoesophageal long-axis view shows the left ventricle and left ventricular outflow tract (LVOT). This view is used to look for obstruction in the outflow tract and aortic insufficiency. Ao, aorta; LA, left atrium; LV, left ventricle; RVOT, right ventricular outflow tract.

regurgitation. The mitral valve is well seen both on the two-chamber view and the long-axis view. This allows better evaluation of the degree of mitral regurgitation, if present, in a second plane apart from the four-chamber view. Regurgitant jets directed anteriorly or posteriorly can better be visualised, and thus can be localised in three dimensions. The same view shows well the membranous part of the ventricular septum, and helps assessment of devices inserted for closure of perimembranous ventricular septal defects, showing the relationship between the device and the leaflets of the aortic valve.

By pulling back the probe to atrial level, and angulating around 90 degrees, a long-axis view of the atrial septum and both atriums is obtained (Fig. 18A-36). This can nicely demonstrate the orifices of both caval veins. It is sometimes necessary slightly to move the probe forward and backward. This view is ideal for demonstrating the sinus venosus defects, along with anomalous connection of pulmonary veins to the superior caval vein.

Transgastric Views

Transgastric views are obtained by advancing the probe into the stomach, flexing it, and pulling it back in the flexed position until it contacts the gastric fundus. The images obtained resemble closely those obtained from subcostal position, albeit that flexibility is reduced for changing the plane of imaging when the probe is in the stomach. The transgastric images are oriented so that, when seen on the screen, the apex is down, the outflow tracts are up, and the left ventricle is on the right side of the screen, thus retaining consistency with the orientation of subcostal images. Depending on the degree of flexion, more anteriorly or posteriorly directed images are obtained.

The short-axis view is usually the first one obtained when the probe is advanced into the stomach and ante-flexed to image the heart. The right and left ventricles and the intervening ventricular septum are shown, with various short-axis planes permitting analysis of the atrioventricular valves, the position of the papillary

Figure 18A-36 This transoesophageal long-axis view is taken at the level of the atrial septum, showing the long axis of the atrial septum separating the left (LA) from the right atrium (RA). The superior caval vein (SVC) is seen entering the right atrium.

Figure 18A-37 The transgastric short-axis view cuts through both the left (LV) and the right ventricle (RV). This view is used for assessing biventricular function.

Figure 18A-39 From transgastric position, it is also possible to cut longitudinally along the left ventricular outflow tract. From this window, it is often possible to obtain good Doppler interrogation of obstructions within the outflow tract. Ao, aorta; LV, left ventricle; RV, right ventricle.

Figure 18A-38 The transgastric view provided a more longitudinal image of the right ventricular outflow tract. From this window, it is often possible to obtain good Doppler alignment to assess any obstruction within the outflow tract. LV, left ventricle; PA, pulmonary trunk; RV, right ventricle; RVOT, right ventricular outflow tract.

muscles, the pattern of the apical trabeculations, and the ventricular relationships (Fig. 18A-37). These views are also used for studying global and regional left ventricular function immediately after discontinuation of cardiopulmonary bypass. Angulating the probe in a long-axis dimension, with different degree of flexion, shows the right and left ventricular outflow tracts (Figs. 18A-38 and 18A-39). From the transgastric views, it is often possible to align a pulsed wave or continuous wave Doppler cursor in order to quantify the degree of obstruction in the outflow tracts, if present. Lack of good alignment between

the signal and the flow can be an important limitation for transoesophageal echocardiography.

SPECIAL USES OF ECHOCARDIOGRAPHY

Post-operative Echocardiography

As has already been discussed extensively, transoesophageal echocardiography has now become the gold standard for post-operative monitoring. The technique plays an important role in the assessment of post-bypass ventricular function, the adequacy of the surgical repair, and detection of any residual lesion that may require immediate revision. After the patient has been transferred to the intensive care unit, echocardiographic evaluation might be required should there be unexplained haemodynamic deterioration. The windows available for imaging the patient in the intensive care unit can be extremely limited due to wound dressings, an open chest, and poor positioning. Despite these limitations, it is possible to get sufficient information in the majority of patients. Should insufficient data be gathered, repeating the transoesophageal interrogation is a good option if the patient remains intubated and ventilated. The aim of the evaluation is, first, to assess ventricular systolic function. Often this will rely on subjective evaluation. If the images are adequate, however, the biplane Simpson's method can be used to quantify ejection fraction. The second goal is to assess any haemodynamically significant residual lesion. Compared to the immediate period after discontinuation from post-bypass, important changes in preload, afterload, and contractility occur over the next 24 to 48 hours. Residual shunts, stenosis, and regurgitation all require exclusion, since these complications can be underestimated during the study performed immediately after completion of post-bypass. The third task is to evaluate ventricular filling and diastolic function. Cross sectional images permit

Figure 18A-40 This apical four-chamber view is taken in a patient with a large pericardial effusion, which surrounds both ventricles and extends to the left ventricular apex. PE, pericardial effusion.

assessment of the filling of the ventricular cavities. Formal assessment of diastolic function should exclude restrictive right ventricular physiology in case of right heart disease, or left ventricular diastolic dysfunction. Pericardial effusions and cardiac tamponade should also be excluded (Fig. 18A-40). Echocardiography in the intensive care unit requires good communication between the echocardiographer and the physician in charge of intensive care so that the question or clinical problem under investigation is well communicated and hopefully answered.

Contrast Echocardiography

Contrast echocardiography requires the injection of a substance that produces echocardiographic opacification of the blood, increasing the contrast between the blood and the surrounding structures. In children, this usually involves the intravenous injection of agitated saline (Fig. 18A-41). The multiple interfaces between the liquid and the air produce an increased backscatter when interacting with ultrasound. The microbubbles are filtered by the pulmonary or systemic capillary beds, and disappear very quickly from the circulation. Carbon dioxide is added to the mixture to reduce the risk of air embolisation should there be a right-to-left shunt. The carbon dioxide is quickly absorbed in the blood when the bubbles disappear. Specialised contrast agents have also been developed. They contain smaller bubbles, which are more stable compared to agitated saline. Their increased stability allows opacification of the myocardium after they have passed through the ventricular cavity, thus permitting study of myocardial perfusion. These modern agents, however, have not thus far been approved for use in children. In children, only agitated saline can be used. The main indication is the detection of right-to-left shunts not seen using colour Doppler interrogation. This can be caused by intracardiac shunts such as a patent oval foramen, or extracardiac shunts, such as

Figure 18A-41 This image shows contrast echocardiography using agitated saline. The right atrium (RA) is opacified with contrast. Some bubbles pass through the atrial septum to fill the left atrium (LA). LV, left ventricle; RV, right ventricle.

arteriovenous malformations, or a left superior caval vein persisting after a bidirectional Glenn shunt.

Stress Echocardiography

Echocardiography is generally performed at rest with the patient lying in the lateral position or on the back, depending on the window used for imaging. For certain indications, like coronary arterial disease, or the evaluation of the haemodynamic significance of certain valvar lesions, studying the heart during stress provides extra information which might help subsequent treatment. Pharmacological stress and exercise echocardiography are the two common stressors used to evaluate the haemodynamic and myocardial responses. Exercise can be performed after a baseline echocardiography on a treadmill or on a bicycle, and immediately after peak exercise the echocardiographic study is repeated with the patient in a supine position. Alternatively, exercise echocardiography can be performed on a supine bicycle, which allows continuous imaging during the test. This implies that the real peak exercise can be recorded, and that the imaging is not performed during the period of recovery. Typical pharmacological stress includes the administration of dobutamine, or vasodilators such as adenosine or dipyridole. In children, the most common indications for a stress test are the detection of vasculopathy after transplantation, or problems with the coronary arteries after operations like the arterial switch procedure or the Ross operation.

Quantitative Echocardiography

Cross sectional echocardiography allows the description of cardiac anatomy in great detail. The first prerequisite in every child is to rule out morphological abnormalities. If present, they should be fully characterized. Apart from morphological evaluation, a full echocardiographic study

should also provide information on haemodynamics, specifically pressures and flows, valvar function such as the degree of stenosis and regurgitation, and ventricular systolic and diastolic function. While morphology is descriptive, functional parameters are quantitative. By combining different M-mode, cross sectional, and Doppler techniques it has become possible to gather quantitative information on the haemodynamic severity of cardiac defects.

Quantification of Echocardiographic Dimensions

Determination of the size of the heart and great vessels is essential for the diagnosis and treatment of congenital cardiac disease. One of the challenges facing the paediatric echocardiographer is the fact that cardiovascular structures grow along with the size of the body. In order to be able to compare measurements, methods need to be developed to normalise cardiac dimensions for growth. As essential as normalisation of the measurements for growth is the standardisation of cardiac measurements. The American Association for Echocardiography has published recommendations for standardisation of echocardiographic measurements, but a lot of relevant structures in children are not included in the description.⁹ So, when using normative data, it is important to perform the measurement exactly the same way as the initial data was obtained. The best way to normalise measurements in children is to use z-scores.¹⁰ The z-score of a variable corresponds to the position of an observed case relative to the mean of the distribution in the population expressed in standard deviations. The z-scores are derived from a large number of normal observations within populations in which the mean and standard deviation are derived as a function of the size of the body. Representing a measurement as a z-score immediately provides the information how the measurement is positioned relative for the mean of the population. A z-score of -4 for the annulus of the mitral valve is four standard deviations below the mean for the normal population. The z-scores can be derived from published normograms or formulas.^{11,12} Ideally, each laboratory performing paediatric echocardiography should be able to establish its own z-scores for use as a reference. The same formula should also be used to calculate body surface area as compared to the normative dataset, as different mathematical formulas have been used for these purposes.

Ventricular dimensions are still commonly measured by the M-mode technique in a large majority of paediatric echocardiographic laboratories. The high frame rate allows accurate recording of events that occur rapidly, such as mural motion, change in cavitory size, and motion of leaflets (Fig. 18A-42). Measurements can be made at precise times within the cardiac cycle. For this reason, an M-mode recording should always be accompanied by an electrocardiogram. End-diastolic measurements are typically made at the onset of the QRS-complex, while maximal mural excursion is often used for the definition of end-systole, which usually corresponds to the end of the T-wave. M-mode measurements can be made in the parasternal short-axis and long-axis cuts at the level of the leaflets of the mitral valve. Cross sectional imaging should be used to align the M-mode cursor so as to avoid oblique cuts. The M-mode measurements are then used to calculate fractional shortening on the basis of left ventricular end-diastolic dimension minus left ventricular end-systolic dimension divided by the left ventricular end-diastolic dimension. It can also

Figure 18A-42 This M-mode tracing is recorded perpendicular to the major axis of the left ventricle just distal to the mitral valve. This image is used to calculate left ventricular dimensions and fractional shortening.

be used to calculate the index of left ventricular mass. Left atrial and ascending aortic dimensions are measured with the M-line at the level of the leaflets of the aortic valve in parasternal long- or short-axis sections (see Fig. 18A-42).

Quantification of Flow, and Identification of Patterns of Flow Normal Doppler Examination

Doppler measures the velocities of blood pools, providing both quantitative and qualitative information. When making such measurements, it is important to recognise certain patterns of flow, which are different within different parts of the circulation. It is also important to have knowledge of the different normal velocities of flow within the circulation. In this section, we discuss the qualitative and quantitative aspects of Doppler echocardiography in the normal heart. We will discuss how normal and abnormal patterns can be differentiated, emphasising the common sites used for interrogation in children with congenitally malformed hearts.

Systemic Venous Flow

The inferior caval vein can be imaged from the subcostal position using colour Doppler, ensuring a low Nyquist limit. When guided by the colour flow, the sample volume of the pulsed wave Doppler can be aligned as well as possible. Usually this will be in the paracoronary view of the inferior caval vein entering the right atrium. The scale should be lowered, and the baseline shifted upwards, as the flow is below the baseline. The superior caval vein can be imaged in subcostal or suprasternal views. From the subcostal position, flow will be towards the transducer, while from the suprasternal notch, it will be away from the transducer. Especially in larger children, it is easier to measure the flow from the suprasternal view. The normal pattern of venous flow is triphasic (Fig. 18A-43). The S wave occurs during ventricular systole, and is caused by atrial relaxation and descent of the tricuspid ring. The D wave occurs during diastole. It corresponds to ventricular filling when the tricuspid valve is open. During atrial contraction, there is a brief period during which flow is reversed in the systemic veins. This corresponds to the A wave. The S and D waves correspond, respectively, to the x and y descents of the jugular venous pulse, while the Doppler A wave corresponds to the venous A wave. There is marked respiratory variation in the velocities, with an increase in S and D velocities with

Figure 18A-43 The subcostal pulsed wave Doppler shows flow through the superior caval vein, which is in the direction of the probe. There is a systolic, as well as a diastolic component, with very limited reversal of flow during atrial contraction.

inspiration. This explains why normal values have been defined during expiration. The value for the S wave is 0.70 ± 0.14 m/sec, while that for the D wave is 0.41 ± 0.09 m/sec. With high heart rates, the S and D flows may be fused and appear continuous.

Abnormal patterns of flow in the caval veins can be seen in the setting of tricuspid regurgitation, which is associated with decreased S flow and increased D flow. When regurgitation is severe, there can be systolic reversal of flow. Abnormalities of right ventricular myocardial relaxation will result in decreased D flow and increased S flow. In those with restrictive right ventricles and increased right atrial pressure, the S flow is decreased, and a large A reversal is present during atrial contraction. Low flow in the hepatic veins can also be studied from the subcostal views. The Doppler waveforms are similar to those seen in the caval veins but with lower velocities.

Abdominal Aorta

From the subcostal position, it is possible to obtain a parasagittal view of the abdominal aorta. Aortic pulsatility can readily be observed using cross sectional imaging or colour Doppler (Fig. 18A-44). Pulsed wave Doppler sampling can be obtained at this site, but it is generally not possible to align the Doppler beam entirely parallel to the flow, so only quantitative information is obtained. The normal abdominal pattern shows a predominant systolic flow, with a very short early diastolic reversal and no additional diastolic flow. Continuous diastolic forward flow occurs in the context of coarctation of the aorta. In this setting, detection of diastolic antegrade flow is considered a good tool for screening. Diastolic reversal or backflow occurs in the context of severe aortic regurgitation, an aortopulmonary shunt with left-to-right shunting, such as seen in the patient with a large persistently patent arterial duct, an aortopulmonary window, aortopulmonary collateral arteries, or Blalock-Taussig or central shunts, or in case of large arteriovenous malformations in the upper part of the body. Flow in the abdominal aorta is reduced in case of low cardiac output.

Pulmonary Veins

The velocity of pulmonary venous flow can be obtained from different windows, but flow is commonly recorded in the right upper or lower pulmonary vein from the apical

Figure 18A-44 Subcostal pulsed wave Doppler of the abdominal aortic flow. Flow is in the direction of the probe. There is a very short early diastolic reversal (arrows), which is normal. There is no significant diastolic flow.

four-chamber view. The normal pattern is triphasic, but there can be a biphasic systolic component. The early systolic peak, S1, corresponds to atrial relaxation. The later systolic peak corresponds to systolic filling of the atrium due to systolic descent of the mitral valve. The diastolic flow corresponds to early diastolic filling, and there is atrial reversal during atrial contraction (Fig. 18A-45). Pulmonary venous flows are abnormal in the context of pulmonary venous stenosis, mitral regurgitation, and left ventricular diastolic dysfunction. Assessment of pulmonary venous flow has become an integral part of the evaluation of left ventricular diastolic function. Normal velocities of pulmonary venous flow are less influenced by respiration compared to systemic venous flow. The velocities, however, change with age, and are also dependent on heart rate.

Atrioventricular Valves

Velocities of flow through the mitral and tricuspid valves are usually best recorded from the apical four-chamber view. The cursor should be positioned at the tip of the leaflets, with the smallest possible sample volume. The flow

Figure 18A-45 Apical four-chamber view of a pulmonary venous tracing. Notice the biphasic pattern of systolic flow, and the monophasic diastolic flow. There is a limited reversal of flow during atrial contraction (arrow). The peak systolic and diastolic velocities are measured, permitting calculation of the ratio of systolic to diastolic peak velocity.

Figure 18A-46 The normal pattern of mitral inflow as imaged from the apical four-chamber view. The peak E-velocity and peak A-velocity are measured, permitting calculation of the ratio of velocities, the E to A ratio. It is also possible to measure the deceleration time of the early peak, and the duration of the A-wave.

through the atrioventricular valves is towards the transducer from the apical position, and hence is displayed above the baseline. The normal pattern shows two waves. The E wave occurs during early filling after valvar opening. The A wave occurs during atrial contraction (Fig. 18A-46). In mid-diastole, there is a period of no flow, or diastasis. Typically, the velocity of the flow across the mitral valve is greater than that measured across the tricuspid valve. The tricuspid inflow, however, varies more significantly with respiration compared to the mitral inflow.

The peak velocities of the E and A waves are influenced by both age and heart rate.¹³ In normal children, the mitral E velocity is larger compared to the A velocity, while in normal newborns the mitral A velocity is larger than the E velocity. This is thought to be related to immaturity of the myocardium, especially in handling of calcium metabolism, resulting in slower early relaxation, and large dependency on filling during the period of atrial contraction. The inflow velocities are used to assess diastolic function, especially of the left ventricle. This is because abnormalities of relaxation, as well as decreased compliance and increased ventricular stiffness, will affect the inflow patterns. Discussion of assessment of diastolic dysfunction, however, is beyond the scope of this chapter. Atrioventricular valvar stenosis is associated with increased velocities of flow, and continuous wave Doppler can be used to quantify the degree of stenosis, as discussed below.

Right Ventricular Outflow Tract and Pulmonary Trunk

Velocities in the right ventricular outflow tract and pulmonary trunk are best recorded from the subcostal position, or from the left parasternal short-axis views. To align better with the flow, it is useful to position the transducer one or two ribspaces lower compared to the standard parasternal position. When the transducer is tilted superiorly, flow through the outflow tract will be aligned with the Doppler beam. Flow is directed away from the transducer, and is displayed below the baseline (Fig. 18A-47). Anterograde flow occurs during systole, although some anterograde flow can occur in late diastole concomitant with atrial contraction during inspiration, as at that time pressure in the right ventricle can exceed diastolic pressure in the pulmonary arteries. This can result in late diastolic opening of the

Figure 18A-47 The pulsed wave Doppler profile of normal flow in the pulmonary trunk as seen from the parasternal short-axis view. The acceleration of flow is slower compared to that seen in the left ventricular outflow tract and the aorta.

pulmonary valve, especially with inspiration when there is increased pulmonary venous return to the heart. Normally there is no flow in the pulmonary arteries during diastole, although a small amount of reversal of flow can occur early after closure of the pulmonary valve due to some back-flow associated with valvar closure. The mean normal peak velocity across the pulmonary valve is 0.9 m/sec, with a range from 0.7 to 1.1 m/sec. If a left-to-right shunt is present, increased flow across the pulmonary valve at increased velocity is noted. This increased velocity needs to be distinguished from associated obstruction in the right ventricular outflow tract. In this setting, cross sectional imaging to look for muscle bundles, infundibular stenosis, pulmonary valvar motion, and to inspect changes in dimension in the supravulvar region, is an important adjunct.

Left Ventricular Outflow Tract, Ascending and Descending Aorta

Velocities in the left ventricular outflow tract are best recorded from the apical five-chamber view. The Doppler velocities recorded from this position appear as a negative systolic waveform. Flow can be recorded below or above the valve, but the peak velocities will be slightly higher above the valve. Flow in the ascending aorta can best be recorded from the suprasternal notch or a high right parasternal position. From these windows, flow will be directed towards the transducer. This view is important should supravulvar stenosis be present (Fig. 18A-48). It is also valuable in those with aortic valvar stenosis, when the jet is often directed eccentrically, and the best alignments with flow can be obtained from these positions. The non-imaging pencil probe can then be used to provide the best possible alignment with the flow. The smaller imprint on the chest allows greater flexibility in manipulation compared to the probes used for imaging. The disadvantage, of course, is that duplex scanning cannot be used to direct the probe. Flow in the left ventricular outflow tract normally occurs only during systole. In the ascending aorta, there can be a very short early diastolic reversal of flow, associated with reversal during closure of the aortic valve. A brief phase of late systolic and early diastolic reversal of flow may result from elastic recoil of the arterial system. Velocities of descending aortic flow are best recorded from the suprasternal notch. The profile is similar to that found in

Figure 18A-48 This normal pulsed wave Doppler profile is obtained from the apical five-chamber view across the aortic valve. Notice the shorter acceleration time compared to the flow in the pulmonary trunk.

the ascending aorta, but flow is in the opposite direction, and with a slightly higher velocity (Fig. 18A-49).

Haemodynamic Measurements

Haemodynamics describe the relationship between pressure and flow. Neither of these values can be measured directly using echocardiography. Based on cross sectional imaging and Doppler, however, it has become possible to estimate flows and pressures. This has several clinical applications, explaining why the echocardiography laboratory is also a haemodynamic laboratory.

The Bernoulli equation describes the relationship between pressure and velocity in a system of laminar flow. It started from the observation that, if a flow encounters a narrowing, the velocity of the flow will increase, but there will be a drop in pressure across the narrowing. This is

Figure 18A-49 The normal pattern of flow in the descending aorta is shown as seen from the suprasternal notch. The flow is going away from the transducer. There is no significant diastolic flow. The velocity of the flow is slightly higher than that in the ascending aorta.

based on the principle of conservation of energy, where the total energy is conserved but there is an increase in kinetic energy, or speed, at the expense of potential energy, or pressure. The Bernoulli equation is $P_1 - P_2 = \frac{1}{2} \rho (V_2^2 - V_1^2)$, where P_1 is pressure proximal to the obstruction, P_2 is pressure distal to the obstruction, V_1 is the proximal velocity, V_2 is the distal velocity, and ρ is the density of the fluid. The formula can be simplified as $\Delta P = 4 V_2^2$.

Despite the formula containing many simplifications, the equation can be used in Doppler echocardiography to predict differences in pressure across stenotic or regurgitant valves,¹² or across ventricular septal defects, arterial ducts, or other communications. The equation, nonetheless, remains a simplification. It has several different potential sources of error.

- Doppler techniques measure the velocity in the direction of the echobeam, so if not well aligned, they may underestimate the true velocity, which will result in an underestimation of the true gradient.
- In the equation, the proximal velocity V_1 is considered to be negligible, and hence can be ignored. This is not the case if V_1 is elevated. Elevated proximal velocities are found when multiple levels of obstruction occur in series, such as with discrete subaortic and valvar aortic stenosis, infundibular and valvar pulmonary stenosis, or aortic stenosis and aortic coarctation. A similar arrangement is found across a valve that is both stenotic and regurgitant, when an intracardiac shunt is associated with pulmonary stenosis, or when valvar gradients are measured during exercise.
- The formula can be used for only for discrete stenosis, since it makes abstractions from the losses of pressure related to viscous forces. These are more important in small stenotic long vessels, as for instance a Blalock-Taussig shunt. The drop in pressure associated with acceleration of flow and friction is also not negligible for orificial diameters of less than 3.5 mm. Potential errors may occur, therefore, when there is critical aortic or pulmonary stenosis.
- The Bernoulli equation should also be used with care in the setting of ventricular systolic dysfunction. In this context, the ventricle may no longer be capable of generating sufficient output, and hence produces low proximal velocities. The reduction of flow across the valve will be associated with a reduction in gradient. In case of ventricular dysfunction, Doppler gradients may be abnormally low, and should be interpreted carefully. In contrast to the adult population, this is more unusual in children.
- A final problem can be the phenomenon of recovery of pressure. As already emphasised, when flow occurs across a narrowing, potential energy is converted into kinetic energy. Distal to the narrowing, however, the vessel widens again, and kinetic energy is converted into potential energy. This phenomenon is called recovery of pressure. Because Doppler techniques do not measure such recovery, they overestimate the degree of stenosis.

Mean Pressure Gradient

The pressure gradient derived from the Bernoulli equation is the peak instantaneous pressure gradient, and not the peak-to-peak pressure gradient as measured during cardiac catheterisation (Fig. 18A-50). The peak-instantaneous gradient derived from Doppler

Figure 18A-50 The peak and mean gradients of flow across the aortic valve in a patient with aortic stenosis.

measurements across a stenosis will always be higher than the peak-to-peak gradient. This means that Doppler interrogation systematically overestimates pressure gradients measured invasively. To overcome this problem, the mean pressure gradient can be calculated by integrating the velocity curve during ejection, and thus calculating the mean gradient. This is the average of all the instantaneous pressure gradients throughout ejection. This is calculated electronically by tracing the Doppler curve. Mean pressure gradients have been shown to correlate better with gradients obtained during cardiac catheterization, and are generally used to assess the severity of a stenosis. The hypertrophic response to an obstructed outflow tract, however, is related more to the peak gradient than to the mean gradient. So, in the decision-making process to judge the severity of a narrowing, both the peak as well as the mean gradient has to be taken into account, as well as the effect on the ventricular muscle.

APPLICATION OF THE BERNOULLI EQUATION IN CLINICAL PRACTICE

For the application of the Bernoulli equation in the context of valvar stenosis, reference should be made to the individual chapters devoted to valvar abnormalities in paediatric cardiac disease. In this part, we focus further on the assessment of right ventricular systolic pressure and pulmonary arterial pressures using Doppler echocardiography, as this is an important aspect in the evaluation of patients with congenitally malformed hearts, where elevated right heart pressures, as well as pulmonary hypertension, can be an important topic.

Estimation of Pressures in the Right Ventricle and Pulmonary Arteries

For the assessment of right ventricular pressures and pulmonary artery pressures, different Doppler measurements can be used. If tricuspid regurgitation is present, and

Figure 18A-51 The tricuspid regurgitant jet used to measure right ventricular systolic pressure. The peak velocity is 2.18 m/sec. This corresponds to a peak gradient of 19 mm Hg. Adding a right atrial pressure of 5 mm Hg gives a right ventricular systolic pressure of 24 mm Hg, which is normal.

at least mild, a continuous wave Doppler signal can be obtained. The four-chamber view is used most commonly, although other views can provide good alignment with the regurgitant jet. The right ventricular systolic pressure can be calculated from the peak velocity of tricuspid regurgitation using the Bernoulli equation by adding the right atrial systolic pressure, as the regurgitant jet is driven by the pressure difference between the right ventricle and the right atrium (Fig. 18A-51). If no direct or indirect measurement is present, right atrial pressure is assumed between 5 to 10 mm Hg. In the absence of right ventricular outflow tract obstruction, it can be assumed that right ventricular and pulmonary arterial systolic pressures are equal. Even in the presence of pulmonary stenosis, however, knowledge of the right ventricular pressure and the gradient across the right ventricular outflow tract will provide an estimate of pulmonary arterial systolic pressure.

If a ventricular septal defect is present, it is often possible to interrogate the flow across the defect. By measuring the peak systolic velocity, the peak instantaneous pressure difference between the left and right ventricles can then be calculated. To estimate right ventricular systolic pressure, left ventricular systolic pressure is assumed to be equal to systemic systolic arterial blood pressure. Subtracting the pressure gradient across the defect from the estimated left ventricular systolic pressure provided the right ventricular systolic pressure. This again is based on several assumptions, which can make the method unreliable. First, the assumption that arterial pressure is equal to left ventricular systolic pressure is only true if there is no left ventricular outflow tract obstruction. Second, if there is a significant delay in the build up of pressure during systole in both ventricles, as in the setting of right bundle branch block, the peak instantaneous gradient measured during systole overestimates the real gradient, potentially missing significant pulmonary hypertension. Third, it can be extremely difficult to align the cursor with the jet of the defect, potentially underestimating the gradient. It is also possible that obstruction may be present across the right ventricular outflow tract.

If the arterial duct is patent, the direction and the velocity of flow measured across the duct can be used to estimate the

pulmonary arterial pressure. When the shunt is right-to-left, or bidirectional, this indicates suprasystemic or systemic pressures in the pulmonary arteries respectively. When the shunt is left-to-right, a Doppler measurement of the flow can be obtained. It can be difficult to align the cursor with the direction of the flow and obtain a reliable Doppler tracing, but in most patients it is possible to obtain a good Doppler tracing. When the duct becomes more restrictive, the flow will become continuous. It can then become difficult to define the peak gradient. In general, it is better to use the mean gradient. Subtraction of this mean ductal gradient from the mean systemic arterial blood pressure gives the mean pulmonary arterial pressure.

The majority of patients have a variable degree of pulmonary regurgitation, from which it is possible to obtain a reliable pulsed wave or continuous wave Doppler signal. This can usually be obtained from the parasternal short-axis view, or sometimes from the subcostal windows. When a good tracing is obtained, two different measurements can be performed. Of these, the peak diastolic gradient between the pulmonary artery and the right ventricle has been shown to correlate highly with the mean pulmonary arterial pressure. This relationship is coincidental, and very fortuitous for the clinical echocardiographer. As the pressure gradient reflects the pressure difference between the pulmonary artery and the right ventricle at that time, right ventricular diastolic pressure should be added to the measurement (Fig. 18A-52). An estimated right atrial pressure is also added. The pulmonary end-diastolic pressure can be estimated based on the pulmonary regurgitant jet by measuring the end-diastolic velocity P . The gradient between the pulmonary arteries and the right ventricle is then provided using the equation

$$\text{PADP} - \text{RVED} = 4V^2$$

where PADP is the pulmonary arterial end-diastolic pressure, V is the end-diastolic velocity, and RVED is the right ventricular end-diastolic pressure. Again, right atrial pressures are used as an estimate for right ventricular end-diastolic pressure but this is not always a good estimate.

Figure 18A-52 Pulsed wave Doppler from the pulmonary regurgitant jet is obtained from a parasternal short-axis view. The maximal velocity is measured to be 1.58 m/sec, which corresponds to a gradient of 10 mm Hg. Adding a mean right atrial pressure of 5 mm Hg predicts a mean pulmonary arterial pressure of around 15 mm Hg.

When pulmonary regurgitation becomes severe, there might be significant shortening of the regurgitant jet due to fast equalization between pulmonary and right ventricular diastolic pressures related to the large regurgitant volume.

Apart from using the Bernoulli equation, there have been attempts to use different Doppler time intervals to try to predict pulmonary arterial pressures. These intervals, however, are influenced by heart rate, contractility, and conditions of loading. When used to predict a change in afterload, the other factors are presumed to be relatively constant, and this is rarely the case. These methods, therefore, are not commonly used in clinical practice.

The Continuity Equation

A second important haemodynamic principle, which has been used in a number of Doppler applications, is the continuity equation. This is based on the principle of conservation of mass within the cardiovascular system, which predicts that the flow will be equal at various points within the circulation. The flow across all four valves within the heart will be equal in the absence of intracardiac shunts or valvar regurgitation. Flow across a fixed orifice is equal to the product of the cross sectional area of the orifice and the velocity of flow. In order to calculate velocity through an orifice, it is necessary to calculate the mean velocity across this area. This can be done by measuring the time velocity integral, which is calculated electronically by tracing the Doppler velocity signal. The stroke volume is the product of the cross sectional area and the time velocity interval. The continuity equation has been used in different echocardiographic applications.

The first is the calculation of stroke volume and cardiac output. This can be performed by obtaining a Doppler signal in the left ventricular outflow tract, usually from an apical four-chamber view, and measuring the time velocity interval. If the diameter of the left ventricular outflow tract is measured, usually from a parasternal long-axis view, the cross sectional area can be calculated as $\pi (D/2)^2$, which is equal to $0.785 D^2$. Then stroke volume is the product of 0.785, the square of the diameter, and the time velocity interval. Multiplying this value by heart rate provides the cardiac output. The same can be done for the right ventricular outflow tract. If there are no intracardiac shunts, or significant valvar regurgitation, the right ventricular stroke volume should be equal to the left ventricular stroke volume. If there is an intracardiac shunt without valvar regurgitation, the ratio of right to left ventricular output should reflect the magnitude of the shunt, or the ratio of pulmonary to systemic flows. In practice, there are a lot of pitfalls associated with this method. In the first place, alignment of flow can be problematic. Second, it can be difficult to measure the diameters of the outflow tract, especially the right ventricular outflow tract, which is in the near field. The assumption that the left and right outflow tracts are circular is also not entirely true. Furthermore, in small children, a small error in measurement of diameter will result in a significant error in the calculation of output, as the error is squared in the formula. These factors explain the high variability of the measurement in children, and especially in infants.

Calculation of Valvar Area

The continuity equation can also be used to calculate the area of a stenotic or regurgitant valve. This is based on the continuity principle of conservation of mass, flow

across a stenotic or regurgitant orifice being the same as an upstream flow across a known area. For instance, when considering the aortic valve, flow across the valve should be equal to flow through the left ventricular outflow tract:

$$\text{Area}_{\text{LVOT}} \times \text{TVI}_{\text{LVOT}} = \text{Area}_{\text{aortic valve}} \times \text{TVI}_{\text{aortic valve}}$$

The area of the aortic valve, therefore, can be calculated as:

$$\text{Area}_{\text{aortic valve}} = \text{Area}_{\text{LVOT}} \times (\text{TVI}_{\text{LVOT}} / \text{TVI}_{\text{aortic valve}})$$

This principle has not gained a lot of popularity in the assessment of paediatric cardiac disease for the same reasons discussed above for the continuity equation. The measurement of flow is more prone to errors than the measurement of gradients. A small error in measuring the left ventricular outflow tract, in particular, can result in significant errors when calculating the valvar area. Calculation of valvar areas, therefore, does not influence decision-making in paediatric cardiology to the same extent as in adult cardiology. There is hope that combining three-dimensional echocardiography will provide more reliable measurements of the left ventricular outflow tract and the aortic valve.

SUMMARY

Combining cross sectional echocardiography with a segmental morphological approach permits fully description of the morphology of nearly all congenitally malformed hearts. Additional imaging techniques can still be required for the assessment of extracardiac anomalies. Despite this, cross sectional echocardiography is the cornerstone for imaging in children with congenitally malformed hearts, and an indispensable tool in their subsequent management.

Three-Dimensional Echocardiography

CHAPTER

18B

GIRISH S. SHIRALI

Appreciation of complex intracardiac anatomy and spatial relationships is inherent to the diagnosis of congenitally malformed hearts. Beginning over 30 years ago, and until recently, the ability of the clinician to image the heart by echocardiography was limited to cross sectional techniques displayed in two dimensions.¹ Such two-dimensional echocardiography has fundamental limitations. The very nature of a two-dimensional slice, which has no thickness, necessitates the use of multiple orthogonal sweeps. The echocardiographer then mentally reconstructs the anatomy, and uses the structure of the report to express this mentally reconstructed vision. This means that the only three-dimensional image of the heart available for diagnosis is the virtual image existing in the mind of the echocardiographer, who then translates this vision into words when preparing the report. It is not easy for an untrained, albeit interested, observer to understand the images obtained in the course of a sweep. Expert interpretation is required. Furthermore, since myocardial motion occurs in three dimensions, two-dimensional echocardiographic techniques do not lend themselves to accurate quantitation.

Recognition of these limitations of cross sectional echocardiography seen in two dimensions led to burgeoning research and clinical interest in three-dimensional echocardiography. Early reconstructive approaches were based on acquisitions of large numbers of two-dimensional images that were subsequently stacked and aligned based on the phases of the cardiac cycle, in this way producing a three-dimensional dataset.²⁻⁴ While these approaches proved to be accurate, the need for time and offline processing equipment imposed fundamental limitations on their clinical applicability. In 1990, von Ramm and Smith published their early results with a matrix-array transducer that provided real-time images of the heart in three dimensions.⁵ While this was an important breakthrough, this transducer was unable to be steered in the third dimension, which has since been termed the plane of elevation. Over the past 5 years, dramatic technological advances have facilitated the ability to perform live three-dimensional scanning, including the ability to steer the beam in three dimensions, and to render the image in real time.⁶

ADVANCES IN TECHNOLOGY

Contemporary transducers based on arrangement of elements in a matrix, piezoelectric materials, and quantitative software are the three elements that have

facilitated enhancements in three-dimensional echocardiography.

Matrix-array Transducers

These transducers comprise as many elements in the elevation dimension as they do in the azimuth dimension, with more than 60 elements in each. While the elements are arranged in a two-dimensional grid, this array generates three-dimensional echocardiographic images. In order to be able to steer in the elevation plane, each element must be electrically independent from all other elements, and each element must be electrically active. The technology and electrical circuitry to insulate electrically, and connect each element, became commercially available in 2002. As a result, these transducers consist of thousands of electrically active elements, each of which independently steers a scan line left and right, as well as up and down.

Piezoelectrical Materials

The piezoelectrical material in a transducer fundamentally determines the quality of the image. Piezoelectrical elements are responsible for delivery of ultrasonic energy into the tissue that is scanned, and for converting waves of reflected ultrasound into electric signals. Their efficiency in converting electrical energy to mechanical energy, and vice versa, is a key determinant of the quality of the image, sensitivity to Doppler shifts, and the ability of transmitted ultrasound to penetrate to increasing depths. In order to create a piezoelectrical effect, these elements must be subjected to the application of an external electric field to align dipoles within polycrystalline materials. For almost 40 years, a ceramic polycrystalline material named lead-zirconate-titanate has been the piezoelectrical material that has enjoyed standard usage in medical applications. This material is a powder that is mixed with an organic binder. The resulting compound is baked into a dense polycrystalline structure. At its best, it achieves approximately 70% alignment of dipoles. This inherently constrains the efficiency of the material to achieve electromechanical coupling.

One example of new piezoelectrical material involves growing crystals from molten ceramic material, resulting in a homogenous crystal with fewer defects, lower losses, and no boundaries between grains.^{7,8} When these crystals are poled at the preferred orientation or orientations, a near-perfect alignment of dipoles is achievable, resulting in dramatically enhanced electromechanical properties.

The efficiency of conversion of electrical to mechanical energy improves by as much as two-thirds to five-sixths when compared to lead-zirconate-titanate ceramics, which are otherwise currently used in ultrasonic transducers. The new piezoelectrical materials provide increased bandwidth and sensitivity, resulting in improvements in both penetration and resolution. The improved arrangement of atoms in these new piezoelectrical materials, and their superior strain energy density, has translated into advances in miniaturisation. These advances led to the availability of a high-frequency matrix three-dimensional transthoracic transducer that has dramatically enhanced the applicability of three-dimensional echocardiography for use in children.⁹ Another example of emerging transducer materials consists of silicon elements. This technology is being developed at the present time.

Software for Quantification

Quantification requires that the software provide the ability to separate out and segment structures of interest from the acquired data. Two-dimensional quantitative techniques are based on geometric formulas that rely on assumptions regarding the shapes of cardiac structures. These assumptions are frequently incorrect. In contrast, three-dimensional acquisitions include the entire extent of the structure, thus minimizing the possibility of foreshortening of the apex or any geometric assumptions regarding shape. Three-dimensional quantitative software has the potential to quantify cardiac structures accurately regardless of their shape. Advances in software for processing three-dimensional data sets have mirrored the rapid advances in transducer technology that have occurred over the past few years.

Three-dimensional volumetric techniques rely on definition of chamber cavities, that is, the interface between blood and endocardium. The software constructs this interface by using a process known as surface rendering, and represents it as a mesh of points and lines. This software-generated mesh is calculated for every frame of acquisition, thus providing a moving cast of the cavity of the ventricle during the cardiac cycle. Since this is digital data, it is easy to compute global and regional volumes, synchrony as well as parametric displays of endocardial excursion, and timing of contraction (Fig. 18B-1).

Tools for three-dimensional quantification of the left ventricle are more technologically advanced than for other

Figure 18B-1 This image demonstrates the capabilities of software that is available for quantitation of left ventricular volumes throughout the cardiac cycle, providing end-diastolic and end-systolic volumes as well as the ejection fraction. The mesh represents left ventricular volume at end-diastole. The cast of the left ventricular cavity consists of segments of varying colours, each of which represents a subvolume of the ventricular cavity based on the 16-segment model that has been standardised by the American Society of Echocardiography. The change in volume of each subvolume is represented graphically, with time on the x-axis and volume on the y-axis.

cardiac structures. Until recently, such tools employed the method of disk summation. With improvements in computing speeds and programming, newer tools have been developed to provide instantaneous tracking of the interface between the blood pool and endocardium at each frame of acquisition. This provides a surface-rendered model that is displayed as a mesh of lines and points. These algorithms, nonetheless, are still based on some basic three-dimensional geometric assumptions regarding left ventricular shape, and therefore they cannot be applied to the right ventricle or to functionally univentricular hearts. Given the complex shape and architecture of the right ventricle, it is unsurprising that tools for quantifying its volume have been slower to mature. Until very recently, these tools utilised the method of disks for volumetrics.¹⁰ Novel software now provides the ability instantaneously to track the interface of blood pool and endocardium at each frame of acquisition (Fig. 18B-2), yielding a surface-rendered model that is displayed as a mesh of lines and points.¹¹

Figure 18B-2 This image demonstrates the capabilities of software that is available for quantitation of right ventricular volume throughout the cardiac cycle. This yields a surface-rendered model that is displayed as a mesh of lines and points. The change in volume of the cavity of the right ventricle is represented graphically, with time on the x-axis and volume on the y-axis. EF, ejection fraction; ED, end diastole; EDV, end diastolic volume; ES, end systole; ESV, end systolic volume.

In a recent development, quantitative software for the mitral valve has been developed. This provides the ability to perform sophisticated analyses of the nonplanar shape of the mitral valvar annulus, and to measure dimensions including annular diameters, lengths of the zone of apposition between the leaflets, and the surface areas of each leaflet.^{12,13} Quantitative techniques have also been developed to provide volumetric measurements of three-dimensional colour flows using non-aliased data.¹⁴

CLINICAL APPLICATIONS IN PATIENTS WITH CONGENITALLY MALFORMED HEARTS

Three-dimensional echocardiographic imaging has three broad areas of clinical application among patients with congenitally malformed hearts, namely, the visualisation of morphology, the quantification of sizes of chambers and flows of blood, and the emerging area of image-guided interventions.

Visualizing Morphology

Dating from an early stage in the development of three-dimensional technology, the structural complexity that is inherent to the congenitally malformed heart has been identified as fertile substrate for exploration using three-dimensional echocardiography.^{15–17}

Atrioventricular Valves

Three-dimensional echocardiography is valuable in delineating the morphology of the atrioventricular valves, with the technique being used at an early stage to delineate congenital abnormalities of the mitral valve,¹⁸ including comprehensive assessment of double orifices.¹⁹ The additive value of the technique, and improved quality of images, was then demonstrated in the intra-operative environment.²⁰ More recently, the technique was shown to be capable of delineating the morphology of the leaflets, cordal attachments, the subcordal apparatus, the mechanism and origin of regurgitation, and the geometry of the regurgitant volume.²¹ In the setting of Ebstein's malformation of the tricuspid valve, the technique was shown to provide clear visualisation of the morphology of the valvar leaflets, including the extent of their formation, the level of their attachment, and their degree of coaptation.²²

Atrioventricular Septal Defect

In patients with atrioventricular septal defect, we have found that three-dimensional echocardiographic imaging provides unparalleled views of the zone of apposition between the superior and the inferior bridging leaflets of the left component of the common atrioventricular valve (Fig. 18B-3). Our experience with a cohort of patients with atrioventricular septal defects²³ showed that gated three-dimensional echocardiographic views could be cropped to reveal the relationships of the bridging leaflets to the septal structures (Figs. 18B-4 and 18B-5). These views have been useful in determining the precise level of shunting, particularly prior to surgical repair. The technique was of particular value in patients with unbalanced defects who were being considered for biventricular repair.

Figure 18B-3 A parasternal short-axis image of the left atrioventricular valve in a patient with atrioventricular septal defect. Asterisks mark the edges of the zone of apposition between the superior and inferior bridging leaflets. A tissue colourisation map has been applied to the image. This has the effect of colouring tissues orange in the near field, near to either the transducer or the front of the image. Tissues that are distant are coloured blue. This is a dynamic after-effect, which means that as the operator rotates, tilts, or otherwise manipulates the image, the colour effect correspondingly changes in real-time. L, left; LVO, left ventricular outflow tract; P, posterior; RV, right ventricle; S, septum.

Figure 18B-4 An apical four-chamber three-dimensional echocardiogram in a patient with atrioventricular septal defect. The bridging leaflets divide the defect into an interatrial (ASD) and interventricular (VSD) component. Note the posterior location of the entrance of the inferior caval vein (ICV) relative to the septal structures. L, left; S, superior.

Atrial and Ventricular Septal Defects

Others have shown that three-dimensional echocardiography provides unique views of the surfaces of the atrial and ventricular septal structures, revealing the holes between

Figure 18B-5 An *en face* view of the left ventricular aspect of the ventricular septum in a patient with atrioventricular septal defect (ASD). The free walls of the left atrium and left ventricle have been cropped. The viewer is looking from left to right. This view demonstrates the disproportion between the shorter inflow (LVI) and longer outflow (LVO) dimensions that characterise the left ventricle in patients with atrioventricular septal defect. Note the crescentic inferior margin of the atrial septum, and the scooped-out edge of the interventricular septum. This view provides excellent anatomic detail regarding the relationships between the bridging leaflets of the common atrioventricular valve (CAVV) and the septal structures. P, posterior; S, superior; VSD, ventriculoseptal defect.

adjacent chambers.^{24,25} The technique is of particular value in demonstrating the morphology of defects within the muscular ventricular septum,²⁶ and in assessing malformations of the outflow tract involving malalignment of the outlet septum.

Aortic Arch, Pulmonary Arteries, and Aortopulmonary Shunts

We have shown (Fig. 18B-6) the value of colour flow Doppler in providing echocardiographic angiograms of the patterns of flow in the obstructed aortic arch, the right and left pulmonary arteries subsequent to the Lecompte maneuver, and across Blalock-Taussig shunts.²⁷ In this recent experience, validation of the diagnosis made by three-dimensional echocardiography was confirmed at surgery, by cardiac catheterisation, or by magnetic resonance or computerised tomographic imaging in two-thirds of the patients.

Aortic Valve and Outflow Tract

Three-dimensional echocardiography has proved accurate in providing measurements of the orifice of the aortic valve, determining the number of valvar leaflets, and identifying sites of fusion between leaflets, as well as demonstrating nodules and excrescences characterizing dysplastic valves.²⁸ The technique has proved of equal value in patients with subaortic stenosis, showing abnormalities of mitral valvar leaflets or cordal attachments, abnormal ventricular muscle bands, and abnormally increased aorto-mitral separation.²⁹

Figure 18B-6 A three-dimensional colour flow, electrocardiographically triggered, full-volume acquisition demonstrating a right sided Blalock-Taussig shunt (BTS). The gray scale image has been suppressed, thus providing an echocardiographic angiogram. The shunt is seen in its entirety from its origin from the brachiocephalic artery (Br) to its insertion. The proximal and distal right pulmonary arteries (pRPA and dRPA, respectively) are well seen. Note the proximity of the superior caval vein (SCV) to the cranial end of the shunt. This dataset can be rotated, tilted, and examined in an infinite number of planes in order to evaluate the lumen of the shunt, and to delineate the location of stenosis. I, inferior; L, left.

Characterisation of Left Ventricular Noncompaction

Three-dimensional echocardiography has enabled diagnosis, and provided detailed characterisation, of the affected myocardium, including easy visualisation of entire trabecular projections, inter-trabecular recesses, endocardial borders, and abnormalities of mural motion abnormalities.³⁰

Quantification of Dimensions, Chambers, Valves, and Function

Left Ventricular Volumetrics

It is feasible to perform three-dimensional echocardiographic measurements of left ventricular end-systolic volume, end-diastolic volume, mass, stroke volume, and ejection fraction in children.³¹ The measurements produced were reproducible, and comparable with those obtained from magnetic resonance imaging. The measurements of volume obtained using three-dimensional echocardiography tended mildly to underestimate those obtained using magnetic resonance imaging. Interestingly, estimates of ejection fraction were in closer agreement. In addition to evaluating the feasibility of performing left ventricular volumetrics, others have addressed the use of resources, the learning curve, and inter- and intra-observer reproducibility.³² Observers were able to obtain, in almost all cases, three-dimensional left ventricular ejection fraction in less than 3 minutes, with the median time being less than 1.5 minutes. They demonstrated a negotiable learning curve, and excellent inter- and intra-observer reproducibility for the performance of three-dimensional echocardiographic left ventricular volumetrics.

Left Ventricular Mass

Studies in adults have validated three-dimensional echocardiography as an accurate method for measuring the mass of the left ventricle.^{33,34} While studies in children have been limited in number and scope, excellent correlations have been shown between left ventricular mass measured by three-dimensional echocardiography and magnetic resonance imaging.³⁵

Left Ventricular Dyssynchrony

The three-dimensional echocardiographic approach to measuring systolic dyssynchrony within the left ventricle uses the model of the left ventricle endorsed by the American Society of Echocardiography, which divides the ventricle into 16 segments.³⁶ The software automatically measures the time of each subvolume from maximal end-diastolic volume to minimal volume, and the standard deviation of these time intervals. The larger the standard deviation, the greater is the implied degree of left ventricular dyssynchrony. In order to control for the wide range of heart rates in children, the time intervals are represented as a percentage of heart rate. The association between left ventricular dysfunction and left ventricular dyssynchrony in children has been explored.³⁷ Normal children had three-dimensional echocardiographic left ventricular dyssynchrony indexes that were below 3%. Among children with dilated cardiomyopathy, there was a clearly defined threshold value of left ventricular ejection fraction, an ejection fraction below 35% being the rule for left ventricular dyssynchrony. In contrast, patients whose ejection fraction was higher than this number had indexes of dyssynchrony that did not differ from those of the normal children who were studied.

Right Ventricular Volumetrics

Until recently, the accuracy of three-dimensional echocardiographic measurement of right ventricular volume and ejection fraction had not been evaluated. This is unsurprising given the complex architecture of the right ventricle, and the technical difficulty of imaging it adequately. A large series of adults has been studied, the patients being compared in terms of volumetric measurements using magnetic resonance imaging and three-dimensional echocardiography using the method of summation of discs.¹⁰ Right ventricular volumes have also been quantified in children with congenitally malformed hearts, using multi-planar reconstruction and tracing with semi-automated detection of borders.¹¹ In both adults and children, excellent correlations were obtained for both right ventricular volumes and ejection fraction. Similar comparisons between three-dimensional echocardiography and magnetic resonance imaging were made for children with functionally univentricular hearts with systemic right ventricles.³⁸ Calculations of diastolic volumes by three-dimensional echocardiography proved to be smaller than those made by magnetic resonance imaging, but systolic volumes and mass showed good agreement. Ejection fraction correlated less well. The intra-class correlation coefficient comparing ejection fraction was 0.64, and the measurements by three-dimensional echocardiography were lower than those obtained using magnetic resonance imaging by 6%. Inter- and intra-observer variability was below 4% for right ventricular ejection fraction, slightly below 2 mL for right ventricular end-diastolic volume, and below a seventh of a mL for right ventricular end-systolic volume. In a reflection

of the speed with which technology is advancing, this study, which was published in March 2008, used a transducer that is already outdated in terms of quality of microelectronics, which translates directly into image quality and frame rates. In addition, the frequencies emitted by the transducer ranged from 2 to 4 mHz. This is probably too low for optimal imaging in most of the children who were studied. Their weight ranged from under 3 kg to a little over 31 kg, with a median weight of 7 kg. It is likely that the improved spatial and temporal resolution, and higher frequency of state-of-the-art transducers and machines that is available today, will lead to further improvements in accuracy.

As these tools become more widely available, user-friendly and accurate, we anticipate the development of new paradigms in the use of quantitative echocardiographic parameters as surrogate measures of outcome in clinical trials in patients with congenitally malformed hearts.

Three-dimensional Colour Flow

Tools for multi-planar reconstruction provide the ability to not only visualise, but also to trace and measure, the area of valvar regurgitant orifices at their narrowest point. While this technique is new, and has not been validated against any gold standard for such measurements, it has been shown to be feasible, has already yielded insights into the shapes of regurgitant jets, and holds promise as a tool to enhance our ability to serially quantify valve regurgitation.^{39,40}

In a series of elegant studies that began in a laboratory setting, and continued through animal models to the bedside of human beings, a technique has been developed and validated for quantifying non-aliased three-dimensional echocardiographic jets of colour flow.⁴¹ In animal studies, measurements that were obtained by three-dimensional echocardiography were compared to those obtained from probes that were directly placed on the ascending aorta to measure flows.¹⁴ Excellent correlation was found between the techniques. Quantification of colour flow has also been validated in adults by comparison to cardiac outputs that were obtained by thermodilution.⁴² Application of this technique to pathologic states could potentially lead to more accurate measurements of regurgitant volumes and fractions.⁴³

Interventions That Are Guided by Echocardiographic Imaging

The high temporal and spatial resolution of transthoracic, and particularly transoesophageal, three-dimensional echocardiography has ignited interest in the potential uses of live interrogation to guide interventions. Already this technique has been used to guide endomyocardial biopsy in children, with no complications.⁴⁴ Specifically, there were no instances of new flail tricuspid valvar leaflets, which might reflect injury or avulsion of cordal structures, or pericardial effusion, which may reflect perforation of the heart. The technique proved to be a valuable modality accurately to direct the bioprobe to the desired site for biopsy within the right ventricle. With increasing familiarity, the need for fluoroscopic guidance was minimised. Three-dimensional echocardiography has also now been used to guide cardiac surgery in animals that have an open chest, but without opening the heart, and without cardiopulmonary bypass.^{45–47}

Figure 18B-7 A live three-dimensional transoesophageal echocardiographic image that was obtained immediately following closure of a fenestrated atrial septum with a cribriform Amplatzer septal occluder. The viewer is located inside the anterior portion of the left atrium, looking rightwards and posteriorly. The entire left atrial (LA) disk of the device is seen, with a central protuberance and the meshwork of metal that constitutes its frame. Part of the inferior portion of the right atrial (RA) disk, and the tricuspid valvar apparatus (TV), are also seen. I, inferior; L, left.

The three-dimensional transducer is directly placed on the heart for these procedures. This experience was validated initially by using three-dimensional echocardiography to guide the performance of common surgical tasks in the laboratory setting. More recently, small atrial septal defects have been closed in pigs. In our own recent experience, we have also been able to obtain spectacular images of cardiac chambers, septal structures, and valves, using live three-dimensional transoesophageal echocardiography to guide manipulation of catheters, puncture of the atrial septum, trans-septal procedures, and closure of atrial septal defects (Fig. 18B-7).⁴⁸

Learning Curve

The learning curve of three-dimensional echocardiography is steep but negotiable. Our experience would suggest that successful implementation requires advocacy, and an investment of time by both echocardiographers and sonographers. The acceptance of the technique is increasing on a global level, albeit at an early stage. We have developed and implemented an interactive teaching course that utilises simulations using three-dimensional echocardiographic data sets with rehearsal and direct mentoring. This has been shown to be useful in overcoming the steep part of the learning curve.⁴⁹

FUTURE DIRECTIONS

Advances in the arena of three-dimensional echocardiography will involve technical enhancements, such as improved speed of acquisition, improved image resolution,

holographic displays, a wide range of software that has been validated for quantification, and enhancements to work flow. Refinements in technology will make high-resolution three-dimensional echocardiography available across the spectrum of sizes of patients. We anticipate a three-dimensional echocardiographic transoesophageal probe that is miniaturised for use in small children. With the growing interest in multi-modality imaging, three-dimensional volumetric and anatomic data will be able to be overlaid onto images and measurements that are obtained from other modalities.

SUMMARY

Important technological advances over the past few years have enabled three-dimensional echocardiography to emerge as a modality that provides additive value in managing patients with congenitally malformed hearts. We anticipate that, with continuing improvements in hardware and software, three-dimensional echocardiography will become, in the near future, an integral part of all standard echocardiographic examinations.

Imaging and Functional Assessment by Novel Echocardiographic Techniques

MICHAEL C. VOGEL

Echocardiography has undergone major progress in recent years. While standard cross sectional echocardiography is still the most often used routine method for screening the anatomy of congenitally malformed hearts, and for evaluation of cardiac function, the use of echocardiography has extended to the operating theatre to review surgical results, to monitor interventions, and to evaluate ventricular function in a much more sophisticated way than conventional echocardiography. These recent developments include intracardiac echocardiography, intra-operative echocardiography using either transoesophageal or intracardiac transducers, real-time three-dimensional echocardiography, myocardial or tissue Doppler, and two-dimensional strain. In this part of our chapter devoted to imaging, I focus on myocardial Doppler and two-dimensional strain based on speckle tracing. These two techniques offer new methods for functional assessment of the heart, and are especially useful in evaluating regional and global function of both the right and left ventricle, as they allow for assessment of ventricular function irrespective of the ventricular shape.

BASIC PRINCIPLES

For myocardial Doppler, the same physical principles apply as in blood pool Doppler. The velocities of the flowing blood are high, but have low amplitude. These velocities are in the region of 1 m/sec across normal heart valves,

and may increase to 6 m/sec across stenosed cardiac valves or narrowed great vessels. When blood pool sonographic Doppler was developed, special filters were used to suppress the signal having low velocity and high amplitude originating from movement of the myocardium. These myocardial velocities typically are in the range of around 10 cm/sec at rest, and may increase to 30 cm/sec under catecholamine-induced stress. It was demonstrated in 1989¹ that the myocardial velocities could be measured by pulsed Doppler sonography, and offered clinically useful information. Filters were developed, therefore, which suppress the high velocities at low amplitude originating from the flow of blood (Fig. 18C-1). After it had become evident that assessment of myocardial velocities was a useful clinical tool, colour Doppler imaging of the myocardium was also developed.² The velocity curves obtained from colour Doppler imaging are smoother than those from pulsed Doppler, and can be easily measured (Fig. 18C-2). Myocardial velocities, nonetheless, may be influenced by factors other than myocardial contraction alone, such as the overall motion of the heart during breathing, cardiac rotation, and motion induced by tethering to adjacent segments.³ Some of these problems of measuring myocardial velocities can be overcome by strain and strain rate imaging,

Figure 18C-1 Pulsed Doppler myocardial velocity obtained from the base of the left ventricle. Velocities of three consecutive heartbeats are displayed. The vertical lines denote the isovolumic contraction and relaxation time. The s-wave represents the systolic myocardial velocity during shortening, the e-wave the early diastolic myocardial velocity during early relaxation of the ventricle, and the a-wave the diastolic myocardial velocity during atrial filling.

Figure 18C-2 Myocardial velocity curve obtained from colour Doppler interrogation of the interventricular septum. Myocardial velocities are recorded at base (yellow) and apex (green). s-, e-, and a-waves are named as above. LV, left ventricle; RV, right ventricle.

Figure 18C-3 Longitudinal strain is obtained as a gradient between velocity 1 (V_1) and velocity 2 (V_2) over a distance (d) of 1 cm. Note that both velocities are well aligned to the Doppler beam.

which is calculated as the gradient in myocardial velocities over a given distance, usually 1 cm.

Strain, notated as ϵ , is dimensionless, as it is calculated as a quotient of velocities (Fig. 18C-3). The first derivative of strain is strain rate. Strain provides information about the overall deformation of the myocardium, while strain rate describes how this deformation occurs over time. Both give different information, first on the degree of deformation, and second, on the time course of this deformation.

The major limitation of any Doppler measurement of myocardial velocities and its derivatives, such as strain and strain rate, is the dependency of the Doppler technique on the angulation of the insonating beam. This is a particular problem in patients with congenitally malformed hearts with abnormal chamber topography and dilated or hypertrophied ventricles, which make it very difficult to place the echocardiographic transducer correctly to align the beam with the myocardial wall.

A novel alternative method to Doppler-based measurement of strain is speckle tracking, which allows estimation of the velocity vector, rather than the velocity component, along the line of the image. This method is based on tracking patterns of radio-frequency imaging.⁴ The algorithm finds the velocity vector by tracking patterns in the radio-frequency image between consecutive frames during the cardiac cycle, and thus makes it possible to find the in-plane frame-to-frame position of a pixel relative to its initial position (Fig. 18C-4). This technique requires high-quality b-mode images recorded at frame rates of at least 60 frames per second.⁵ With this method, deformation can be assessed in two directions simultaneously, such as radial and longitudinal. By convention, this method has been named two-dimensional strain.

Figure 18C-4 Speckle tracking of the left ventricle in a short axis. The coloured dots show the myocardium in which the ultrasonic speckles are examined. The arrows indicate the direction of deformation in the myocardium.

EXPERIMENTAL AND CLINICAL VALIDATION OF MYOCARDIAL DOPPLER AND SPECKLE TRACKING

Measurement of myocardial velocities, assessment of longitudinal strain by estimating myocardial velocity gradients, and two-dimensional strain by speckle tracking, have all been validated experimentally.^{6–8} These experimental validations were achieved by comparison of the novel echocardiographic techniques to pressure-volume loops obtained using conductance catheterisation, or using sonomicrometric crystals on the epicardium to quantify myocardial deformation.

Gorcsan et al were the first to validate colour-coded myocardial velocities for the assessment of regional and global left ventricular function.⁶ Peak systolic myocardial velocities increased with dobutamine and decreased with esmolol, while simultaneously measured end-systolic elastance, by use of a conductance catheter, correlated well with these changes. Regional left ventricular peak systolic velocities mirrored changes in myocardial length as measured by the crystals placed in the respective myocardial segments. The first clinical validation of myocardial Doppler was achieved by comparing transmural myocardial biopsies obtained during coronary arterial bypass surgery with myocardial Doppler tracings.⁹ The histological findings were compared to systolic and diastolic myocardial velocities measured the day before surgery, revealing significant relationships between systolic and early diastolic myocardial velocities and beta-adrenergic receptor density, and the proportion of interstitial fibrosis. The study proved that systolic and diastolic myocardial velocities in humans are dependent on the number of functioning myocytes, and the density of myocardial β -adrenergic receptors.

Doppler-derived longitudinal strain was validated experimentally using ultrasonic crystals placed near the left ventricular apex and base.⁷ During ischaemia induced by occlusion of the anterior interventricular artery, the apical myocardium became dyskinetic. Doppler-derived longitudinal strain reacted the same way as the crystals. Thus, measurement of myocardial deformation by strain was shown to detect

changes in regional motion affected by ischaemia. The study also demonstrated the load-dependency of myocardial velocities and Doppler-derived strain, and confirmed the techniques to be dependent on the angle of insonation, thus limiting their clinical applications.

Because of this, speckle tracking was developed and validated to assess deformation independent of the angle of insonation.⁸ Again, sonomicrometric crystals were used as reference, and their changes during inotropic modulation and ischaemia were compared to changes in radial and longitudinal strain. Good agreements were obtained for measurements of both radial and longitudinal strain, and good correlations shown between ultrasonic strain as revealed by speckle tracking and deformation of the crystals.

Although these studies demonstrated the accuracy of myocardial velocities derived by Doppler and speckle tracking, as well as strain, the methods were found to be load-dependent. As such, they offered little advantage over traditional indexes, such as ejection or shortening fraction

for evaluating global ventricular function.¹⁰ Measurements of myocardial contraction during the isovolumic period are likely to be more robust. One of the commonest measured isovolumic indexes remains $dp/dt_{\max}$, which can only be assessed by invasive techniques.¹¹ After we had noticed that the ventricular myocardial velocity during isovolumic contraction increased more markedly than the peak systolic velocity during dobutamine stress, we used myocardial Doppler to measure the acceleration of the myocardium during isovolumic contraction, in other words isovolumic acceleration. Subsequently, we validated experimentally isovolumic acceleration as an index of contractile function, comparing it to myocardial acceleration and velocities measured during the ejection phase.¹² As the independent index of contractility for comparison of myocardial Doppler data, we used pressure-volume analysis, derived by conductance catheter, measuring in this way end-systolic and maximal elastance in both ventricles.^{13,14} Our studies confirmed that small changes in contractile function during beta blockade or stimulation of beta

Figure 18C-5 Measurement of myocardial isovolumic acceleration (IVA). The blue circle indicates where isovolumic acceleration can be identified as the first upstroke in the velocity curve preceding the s-wave. Average acceleration is measured from the time (t) of onset of the (positive) velocity during isovolumic contraction to the point in time of the peak of this velocity. The green line indicates the line between zero and peak velocity along which the acceleration is measured.

Figure 18C-6 Simultaneous velocity curves by myocardial Doppler and end-systolic pressure volume relations (Ees) obtained by conductance catheterisation at baseline and during an infusion of esmolol. Isovolumic acceleration is lower during esmolol and Ees decreases likewise.

Figure 18C-7 Simultaneous velocity curves by myocardial Doppler and end-systolic pressure volume relations (Ees) obtained by conductance catheterisation at baseline and during an infusion of dobutamine to increase contractile function. During dobutamine infusion both isovolumic acceleration and Ees are significantly higher than at rest.

receptors could be detected by measuring isovolumic acceleration (Fig. 18C-5 to 18C-7). Importantly, changes in pre- and after-load in a physiological range (Figs. 18C-8 and 18C-9) did not affect isovolumic acceleration, while the myocardial Doppler-derived indexes of the ejection phase were all influenced significantly by these changes. These experimental findings of the independence of measurements of isovolumic acceleration from conditions of loading were subsequently confirmed in healthy humans, as well as in patients with abnormal loading conditions.^{15,16}

We also performed a clinical validation of isovolumic acceleration in patients with transposition subsequent atrial redirection procedures, in which the morphologically right

ventricle continues to support the systemic circulation.¹⁷ As some of these patients develop systemic ventricular dysfunction in the second, third, or fourth decade of life, it is of clinical interest to assess prospectively their contractile reserve. From 80 such adults, we recruited 12 who simultaneously underwent a study using conductance catheters and myocardial Doppler. At rest, as well as during β -receptor stimulation using dobutamine, we analysed pressure-volume relations and isovolumic acceleration. Both parameters of contractile function increased significantly during β stimulation (Fig. 18C-10). This showed, first, that isovolumic acceleration can detect changes in contractile function in the human, and second, that measurement of the contractile reserve in patients with a systemic morphologically right ventricle has a clinical value. Critics have claimed that isovolumic acceleration may not be due to a ventricular event. We have demonstrated

Figure 18C-8 Simultaneous myocardial velocity (upper panel) and right ventricular volume tracings during preload reduction produced by inflating a balloon in the inferior caval vein to reduce venous return. Up to a volume reduction of 50%, isovolumic acceleration does not change significantly, demonstrating that it is unaffected by preload changes in a physiological range. When right ventricular volumes are reduced by more than 50%, isovolumic acceleration is also affected.

Figure 18C-9 Myocardial Doppler tracing from the base of the left ventricle during an increase in afterload produced by inflating a balloon in the ascending aorta. While diastolic velocities decrease markedly, isovolumic acceleration stays constant for 15 heartbeats. At the same time, left ventricular volume increased by 30%, and isovolumic acceleration was unaffected by this change in afterload.

Figure 18C-10 Correlation between change in isovolumic acceleration (IVA) and change in E_{es} in 12 patients with transposition after a Mustard operation during a 10-minute infusion of 10 μ g dobutamine/kg/min. r is the correlation coefficient (0.68).

experimentally, using simultaneous recordings of right ventricular pressure and myocardial Doppler, that isovolumic acceleration occurs immediately before the ventricle builds up pressure to eject blood, which may be an explanation for the relative insensitivity of isovolumic acceleration to changes in conditions of ventricular loading (Fig. 18C-11). In a patient with complete heart block, we found no signal of isovolumic acceleration during atrial contraction when we had turned off the pacemaker. Isovolumic acceleration reappeared with the first ventricular escape beat (Fig. 18C-12).

Experimental and clinical data suggests, therefore, that isovolumic acceleration provides a robust measurement of left or right ventricular contractile function, with a sensitivity approaching or exceeding those indexes traditionally measured using invasive techniques. During these experiments, we also noticed a dependency of isovolumic acceleration on the heart rate, which increased during atrial pacing. This suggested that we could non-invasively assess the force-frequency relation.¹⁸ This force-frequency relation is a fundamental physiological parameter of myocardial function.¹⁹ Figure 18C-13 illustrates a typical example of this ventricular phenomenon. We found that isovolumic acceleration increased significantly with heart rate during incremental

pacing in both ventricles, mirroring changes in dP/dt_{max} . The normal pattern is for increasing development of force during incremental tachycardia to a point of maximal development, beyond which force then decreases with ongoing increases in heart rate.^{19,20} An abnormal force-frequency relationship has been found in patients with dilated and hypertrophic cardiomyopathies, and in those with cardiac failure.^{21,22} Until now, the force-frequency relation has either been assessed on the explanted myocyte, or invasively using dP/dt_{max} as a measurement of contractile force.^{23,24} Subsequently the force-frequency relation could be measured non-invasively by assessing isovolumic acceleration in normal subjects, as well as patients with functionally univentricular hearts.²⁵

NORMAL CARDIAC FUNCTION ASSESSED BY MYOCARDIAL DOPPLER AND TWO-DIMENSIONAL STRAIN

The myocardial Doppler-derived isovolumic acceleration, systolic velocities, and strain, as well as two-dimensional strain, change with age.²⁶ Thus, appropriate reference values need to be used for those of different ages.^{27,28} By convention, systolic velocities, caused by shortening of

Figure 18C-11 Simultaneous recording of right ventricular pressure (blue), electrocardiogram (green), and a myocardial velocity curve (white) obtained from the base of the right ventricle. The pressure signal from the conductance catheter was fed into the echocardiography machine. The yellow line identifies the onset of isovolumic acceleration, which occurs simultaneously with the onset of pressure rise in the right ventricle (RV). Both isovolumic acceleration and the right ventricular pressure curve start to rise at the onset of the R-wave in the electrocardiogram.

Figure 18C-12 Myocardial Doppler curve tracing (yellow) from the base of the left ventricle in a 12-year-old boy with complete heart block during pacemaker testing. When the pacemaker is switched off there is no QRS complex on the electrocardiographic tracings but a p-wave can be recognised. Just as the first ventricular escape beat appears, isovolumic acceleration can be seen to reappear on the myocardial Doppler velocity curve as well demonstrating the isovolumic acceleration is not related to atrial activity but is a ventricular event.

Figure 18C-13 Simultaneous force-frequency curves obtained by pressure tracings in the left ventricle to determine dp/dt and by measurement of isovolumic acceleration from the base of the left ventricle during atrial pacing in a 15-kg pig. With each increment in heart rate (by 20 beats/min), dp/dt and isovolumic acceleration increase to plateau at a rate of 180 beats/min.

the myocytes, are displayed as positive waves above the zero line, and diastolic velocities, due to relaxation of the myocytes, are displayed as negative waves below the zero line (Fig. 18C-14). For longitudinal strain, commonly assessed in the four-chamber view, the convention is different. Deformation during systolic shortening of the myocytes is displayed as a negative curve (Fig. 18C-15) below the zero line, while deformation during diastolic lengthening is displayed as a positive curve. This is because most cardiologists imaging adults look at the heart upside down in the four-chamber view. In contrast, most cardiologists imaging congenitally malformed hearts use anatomic views in the four-chamber view. Despite this difference, the convention of displaying velocities of shortening above the zero line as positive velocities, and velocities of lengthening of myocardial fibres as negative, has been accepted by cardiologists evaluating congenitally malformed hearts.

Myocardial velocities of shortening can be displayed in a different way, which facilitates recognition of abnormalities

Figure 18C-14 Myocardial Doppler velocity tracing in a 10-year-old healthy boy obtained at the base of the right ventricle. Note that systolic velocities are displayed above and diastolic velocities below the zero-line.

Figure 18C-15 Longitudinal strain curve obtained from myocardial velocities in the same volunteer. Note that the deformation during systole by myocardial shortening is displayed below the zero-line.

of ventricular mural motion. The integral of myocardial velocity data displays the distance a piece of myocardium covers during movement from base to apex. Online calculation makes possible instant recognition of abnormalities of wall motion (Fig. 18C-16). The different distances are colour-coded. As only the velocities directed from base to apex are integrated, any piece of the myocardium which does not shorten from base to apex in systole remains grey. Thus, areas of abnormal motion, which paradoxically lengthen in systole when the remainder of the myocardium is contracting, can be readily identified (Fig. 18C-17).

In a normal pulsed wave Doppler, or colour Doppler, myocardial velocity tracing, it is possible to discern a positive velocity during isovolumic contraction, a positive systolic velocity, known as the s-wave, an early negative diastolic velocity, the e-wave, and a negative diastolic velocity during atrial contraction, the a-wave. In a normal morphologically right ventricle, there is no discernible isovolumic relaxation time, while a small notch can be seen in the tracing of myocardial velocity obtained from the left ventricle, the notch identifying the end of isovolumic relaxation, which begins immediately following the crossing of the zero line by the velocity of the s-wave (Figs. 18C-18 and 18C-19).

Figure 18C-16 A, In the middle, a standard myocardial velocity curve at the base (yellow) and apex (green) of the left ventricle is displayed. To the left of this curve, the left ventricle is displayed in a two-chamber view. The free wall is colour coded with each colour band representing the integral of the systolic myocardial velocity. This velocity integral displays a distance. B, On the right side, the schematic drawing illustrates the distance a piece of myocardium moves from base to apex during systole.

Figure 18C-17 Wall motion abnormality in the right ventricle of a 31-year-old patient with transposition who had undergone a Mustard procedure at the age of 18 months. On the right side, the myocardial velocity curve at base (yellow) and apex (green) is displayed. Note that at the apex there is a negative wave indicating lengthening at systole and a positive velocity indicating shortening during diastole in contrast to the normal myocardial velocity at the base (displayed in yellow). On the left hand side in the lower panel, tissue tracking demonstrates shortening at the base, which is colour encoded in yellow and red, while almost half of the free wall of the right ventricle is displayed in grey (without colour coding), indicating no shortening in systole. This corresponds to the green velocity on the right.

The normal values for isovolumic acceleration, myocardial velocities, and strain and strain rate are listed in Table 18C-1. In the normal heart, there is a gradual decrease of systolic and diastolic myocardial velocities from base to apex (Fig. 18C-20). In contrast, longitudinal strain, which represents a velocity gradient, changes little from base to apex in either ventricle (Fig. 18C-21).

Normally isovolumic acceleration, myocardial velocities, and longitudinal strain are higher in the morphologically right than in the left ventricle. This may reflect the basic physiology of the pattern of contraction of the ventricles, which is determined by the orientation of the myocytes

Figure 18C-18 Normal myocardial velocity curve from a 16-year-old healthy volunteer obtained at the base of the right ventricle. Note that there is no identifiable isovolumic relaxation period, which is characteristic of a right ventricle functioning normally.

Figure 18C-19 Normal myocardial velocity curve from the same volunteer obtained at the base of the left ventricle. Note that in the myocardial velocity tracing from the left ventricle an isovolumic relaxation wave (ellipses) can be identified.

TABLE 18C-1

MYOCARDIAL DOPPLER STRAIN AND STRAIN RATE
NORMAL VALUES

	Right Ventricle	Left Ventricle
Isovolumic acceleration, m/sec ²	1.8 ± 0.4	1.0 ± 0.3
s-Wave, cm/sec	11.5 ± 0.4	8.4 ± 0.4
e-Wave, cm/sec	14 ± 0.4	12 ± 0.4
a-Wave, cm/sec	4.5 ± 0.4	4.5 ± 0.4
Longitudinal strain	45 ± 13%	25 ± 7%
Radial strain	—	57 ± 11%
Strain rate	2.8 ± 0.7	1.9 ± 0.7
Radial strain rate	—	3.7 ± 0.9

Figure 18C-20 Myocardial velocity curve from the same volunteer with myocardial velocities recorded at the base (yellow), middle (green), and near the apex (red) of the right ventricle demonstrating a gradual decrease of isovolumic acceleration, systolic and diastolic velocities from base to apex.

Figure 18C-21 Longitudinal strain curves of the right ventricle in the same person. Note that there is little change in maximal systolic strain between base (yellow), middle (green), and apex (red) of the right ventricle.

and ventricular morphology.²⁹ With the myocardial Doppler technique, we image longitudinal function when sampling in the four-chamber view. As the main force to eject blood from the morphologically right ventricle is longitudinal shortening of the myocytes, causing the base

and the tricuspid valve to move towards the apex, it is not surprising that longitudinal deformation and myocardial velocities are higher in the morphologically right ventricle than in the left. In addition to myocardial velocities and strain, isovolumic acceleration is also higher in the right than in the left ventricle. This is in keeping with experimental data,³⁰ which shows that twitch velocities measured experimentally in the right ventricle exceed those of the left ventricle. In the left ventricle, only the subendocardial and subepicardial myocytes are aggregated in longitudinal fashion, with an important contribution to the ejection of blood provided by the circumferential fibres. Thus, radial function is the predominant functional component in the left ventricle, which can explain the fact that longitudinal myocardial velocities and longitudinal strain are lower in the left than in the right ventricle.

With speckle tracking, a velocity vector is tracked, which later allows for measurement of both radial and longitudinal velocities. The underlying principle of measurement of velocity by speckle tracking is different. For this reason, myocardial velocities are lower than those measured by the Doppler technique (Fig. 18C-22). As these velocities are independent of the angle of insonation, velocities in the longitudinal direction from base to apex, acquired from a standard apical four-chamber view, are not different from those acquired from a subcostal view, where the heart is imaged from a different angle (Fig. 18C-23).

ACQUISITION OF MYOCARDIAL DOPPLER AND SPECKLE TRACKING DATA FOR LATER ANALYSIS

There are some important points to consider in order to avoid pitfalls during recording of myocardial Doppler and two-dimensional strain data. For both techniques, temporal resolution is critical, and thus frame rate needs to be as high as possible. A desirable frame rate for myocardial Doppler-based isovolumic acceleration, velocity, and strain measurements is 180 frames per second, or more. This can be achieved with most commercially available echocardiographic machines by using a narrow sector of the b-mode image to image separately the free walls of the right and left ventricles and the septum (Fig. 18C-24). Typically, the heart is initially imaged in a four-chamber view to provide an overview of the anatomy. In a second step, the image sector is narrowed down just to image the structures to be analysed by myocardial Doppler. Optimal gain setting is important, focussing on a good delineation of the border between blood pool and the endocardium. The gain should be as low as possible to avoid signals from the blood pool, which potentially can interfere with the ultrasonic signal from the endo- or myocardium. This is especially important in patients with a poorly functioning ventricle and low velocity intracardiac flow, such as those with dilated cardiomyopathies.

As myocardial velocity and strain measurements are based on the Doppler principle, the most important point is to achieve an optimal angle of insonation relative to the myocardium. A deviation between the angle of the ultrasound beam and the myocardium of 15 degrees at most is acceptable. Anything larger makes measurements unreliable. In most clinical situations, these goals can be achieved using transthoracic imaging. It is generally possible also to acquire data by transoesophageal imaging,

Figure 18C-22 Comparison between speckle tracking (A) and colour-coded myocardial Doppler-derived myocardial velocities (B) at the base of the right ventricle in a healthy volunteer. Note that the curves look similar while the velocities obtained from speckle tracking are generally lower in systole as well as diastole.

Figure 18C-23 Speckle tracking-derived myocardial velocities in the left ventricle (A1 and A2) obtained from a standard apical four-chamber view (left) and from a subcostal view (right). As the velocities are independent of the angle of insonation, both velocities are similar with a small difference in peak systolic velocity and no difference in early diastolic velocity or a-wave. Similar findings are displayed in B1 and B2, obtained for speckle tracking-derived myocardial strain using the same windows.

Figure 18C-24 Acquisition of data suitable for speckle tracking analysis. In order to obtain a frame rate in above 60 frames per second, the right ventricle (A) and the left ventricle (B) need to be imaged separately. Gain settings need to be optimised to have little or no blood pool signal and to delineate the endocardium.

but the measurements from this data differ from those obtained from transthoracic imaging, and different normal values have to be used for comparison.³¹

Longitudinal strain and strain rate data are derived from myocardial velocities at different locations in the myocardium, usually 1 cm apart. Ideally the angle of insonation should be the same for both velocities. If the difference in the angle between the two velocities, which

are compared, becomes too large, longitudinal strain measurements may become impossible (Fig. 18C-25). The ribs can interfere with the ultrasonic signal during imaging of the ventricles, so this also needs to be avoided. An m-mode tracing can be used to identify artefacts, and distinguish these from true myocardial motion (Fig. 18C-26).

Acquiring data for two-dimensional strain analysis by speckle tracking is generally easier, as the technique is

Figure 18C-25 Left ventricular strain measurement from myocardial Doppler imaging in a healthy volunteer at the base (yellow), middle (green), and near the apex (red). The circles in the b-mode image (A) represent the points where the myocardial velocities which are used to calculate the velocity gradient (strain) are sampled and the lines illustrate the angle relative to the ultrasound beam. As the ultrasound beam at the base is almost 90 degrees in relation to the sampling point the resulting strain curve (B) is inverted and thus (paradoxically) positive and even at an angle of about 45 degrees (green) the curve remains inverted. Further to the apex the sampling is done at an angle of about 15 degrees and a normal strain curve results demonstrating myocardial shortening during systole.

Figure 18C-26 In the b-mode image on the left an artefact most likely caused by a rib can be seen indicated by an arrow which interferes with the Doppler signal from the myocardium. Subsequently no myocardial velocity can be measured at this point.

independent from the angle of insonation, but similar principles hold true as for myocardial Doppler imaging. The frame rate of the b-mode image should be above 60 frames per second. This again can only be achieved by narrowing the sector of the heart to be imaged in most commercially available echocardiographic machines. In practise, this means that the right and left ventricle need to be imaged separately, as a recording of the entire four-chamber view is rarely possible at a high frame rate. Gain settings are as important for speckle tracking imaging as for myocardial Doppler. They should be as low as possible, with the blood pool clearly being black, allowing excellent definition of the border between blood and myocardium.

CLINICAL USE OF MYOCARDIAL DOPPLER ECHOCARDIOGRAPHY AND TWO-DIMENSIONAL STRAIN

The new myocardial Doppler and speckle tracing techniques offer information on both regional and global function. Unlike the ejection fraction, they are not dependent on geometrical assumptions, and as such are independent of the shape of the ventricle. Thus, they can be applied equally to the morphologically left and right ventricle, as well as functionally univentricular hearts. This makes them ideally suited for the assessment of patients with congenitally malformed hearts. Many such patients have undergone surgical intervention, often with production of abnormalities of ventricular mural motion. This may be due to patches used to close ventricular septal defects or enlarge outflows, scars in the myocardium, abnormal filling, or disturbances of electrical activation. While abnormal regional function has been reported in those with transposition after atrial repair using invasive techniques,³² data obtained by non-invasive imaging has been scarce. The same holds true for analysis of regional wall motion in the setting of acquired disease, such as in those affected by Kawasaki disease.³³ Before the advent of myocardial Doppler techniques, analysis of regional function in these patients required time-consuming analysis of mural motion from b-mode images, which were semi-quantitative.^{34,35}

One of the first clinical applications of myocardial Doppler in congenitally malformed hearts was in patients with tetralogy of Fallot.³⁶ This study not only demonstrated a high prevalence of post-operative abnormalities of right ventricular mural motion (Fig. 18C-27), but also showed for the first time an association between these mechanical abnormalities and abnormalities of electrical de- and repolarisation. Following this proof of a mechano-electrical interaction, an interesting therapeutic concept evolved. To reduce risk of sudden unexpected death,³⁷ and to improve

Figure 18C-27 A, B-mode image with colour-Doppler coded myocardium and myocardial Doppler velocity tracing (left) and speckle tracking with speckle-derived velocity tracing (right) in a 27-year-old patient who underwent surgical repair of tetralogy of Fallot with a transannular patch at age 21 months. His electrocardiogram had a right bundle branch block pattern and the maximal QRS duration was 163 ms. The myocardial velocity curve at the base (green) is normal, while the myocardial velocities measured near the apex (yellow) are inverted with a negative s-wave (indicating lengthening during systole) and a positive e-wave (indicating shortening during diastole) representing a wall motion abnormality (ellipse). B, The wall motion abnormality in the apical third of the right ventricle can be identified easily by the red colour indicating lengthening in systole and shortening in diastole. The myocardial velocities derived from the speckle tracking demonstrate again the reversed myocardial velocities in systole and diastole in the same anatomic segment of the right ventricle and the abnormal velocity distribution is identical to the abnormal distribution of the Doppler-derived myocardial velocities in A.

mechanical function in patients with post-operative right bundle branch block, atrioventricular pacing was successfully used in selected patients.³⁸ Preliminary clinical data is promising, and may offer a new option in such carefully selected patients.³⁹ Appropriate selection of patients who may benefit from this expensive and complex new therapy is mandatory, and can be achieved by applying the myocardial Doppler techniques.⁴⁰ Another important clinical problem in patients with tetralogy having significant post-operative pulmonary regurgitation is the optimal timing of replacement of the pulmonary valve. Previous studies using nuclear medicine or magnetic resonance imaging suggest that replacement offers little benefit if the right ventricular ejection is low, less than 40%, and right ventricular volume is in excess of 170 mL/cm² of body surface area.^{41,42} Many patients with severe pulmonary regurgitation have a dilated right ventricle and tricuspid valve, which in turn leads also to tricuspid regurgitation. In this situation, the loading conditions of the right ventricle are markedly altered, which makes difficult the application of load-dependent indexes of right ventricular function.⁴³ By altering loading conditions, severe tricuspid regurgitation may mask right ventricular dysfunction. Thus, load-dependent indexes like myocardial Doppler-derived peak myocardial velocities may be normal, while load-independent isovolumic acceleration is markedly reduced, suggesting a reduced contractile function (Figs. 18C-28A and B). Indeed, in a substantial number of patients with pulmonary regurgitation, we found evidence of ventricular dysfunction when applying a relatively load-independent index of contractility.⁴⁴ Isovolumic acceleration was lower in all patients with tetralogy compared to normals, and correlated with the severity of pulmonary regurgitation, whereas the load dependent systolic velocities, strain and strain rate, which were all abnormally low, failed to correlate

significantly with the severity of the regurgitation. If untreated, pulmonary regurgitation will lead to dilation of the right ventricle, which can influence left ventricular wall motion and function.⁴⁵ Besides right bundle branch block and a duration of the QRS complex in excess of 180 msec, left ventricular dysfunction has been recognised as a risk factor predisposing to sudden unexpected premature cardiac death. This may be related to left ventricular dyssynchrony.⁴⁵

Abnormalities of ventricular mural motion have also been reported using invasive techniques in patients with transposition who remain with a systemic morphologically right ventricle following atrial repair.³² Using the new myocardial Doppler methods, these abnormalities can more easily be evaluated non-invasively (Fig. 18C-29). Patients with abnormal mural motion in the systemic morphologically right ventricle also have a reduced global function, with abnormally low isovolumic acceleration. This finding is consistent with previous studies that examined excursion of the tricuspid valve using m-mode echocardiography.⁴⁶ An important contribution to the failure to augment stroke volume during exercise in these patients is the inability of the systemic venous atrium to contract and to expand, in particular in the patients following the Mustard repair.⁴⁵ The fact that the systemic and pulmonary venous atriums contribute little or nothing to ventricular filling can also be demonstrated by myocardial Doppler. The majority of patients after a Mustard procedure have no discernible a-wave (Fig. 18C-30) in the myocardial Doppler tracing, suggesting absence of active atrial contribution to ventricular filling.⁴⁷ By contrast, most patients after a Senning repair, in whom autologous tissue has been used to redirect the venous returns, have a well-identified a-wave on their ventricular myocardial Doppler tracings.

Figure 18C-28 A, B-mode and colour (blood-flow) Doppler obtained from a 31-year-old patient who underwent surgical repair of tetralogy of Fallot with a transjunctional patch at age 24 months. He has severe pulmonary incompetence and the blood flow colour Doppler demonstrates significant tricuspid regurgitation caused by the dilated right ventricle and tricuspid valve. B, The myocardial Doppler trace obtained at the base of the right ventricle demonstrates a normal systolic velocity of 10.5 cm/sec and a normal early diastolic velocity (12.3 cm/sec) but a very low isovolumic acceleration of 0.3 m/sec² (normal for this age range 1.6 m/sec²), illustrating a reduced contractile function.

Figure 18C-29 Myocardial Doppler tracing from the right ventricle of a 29-year-old patient with transposition who had undergone a Senning procedure at the age of 19 months. The yellow velocity curve has been obtained from the base and the green one from the middle of the right ventricle. The velocity curve at the base is normal while in the middle of the ventricle the s-wave in late systole is reversed as is the early diastolic velocity. Note also that a clear a-wave can be seen at the base.

Figure 18C-30 Myocardial velocity tracing (yellow) obtained from the left ventricular base in a 30-year-old patient with transposition who had undergone a Mustard procedure at the age of 17 months. Note that there is no myocardial a-wave, while a p-wave can be seen in the simultaneously recorded electrocardiogram (green).

A substantial number of patients with functionally uni-ventricular hearts following conversion to the Fontan circulation have abnormalities of ventricular mural motion, with these being associated with abnormal filling of the dominant ventricle (Figs. 18C-31 and 18C-32).^{48,49} Again, the new myocardial Doppler techniques allow for non-invasive diagnosis of these abnormalities,⁵⁰ and are thus much better suited to serial follow-up of these patients, who have a constant rate of attrition,⁵¹ and in whom cardiac failure is a major cause of late death. Failure of the Fontan circulation can lead to failure of other organs, and lead to serious symptoms, such as protein-losing enteropathy.⁵¹ Anecdotal data shows that epicardial pacing to resynchronise the dominant ventricle may improve ventricular function and abolish the protein-losing enteropathy.⁵²

Congenital valvar aortic stenosis changes left ventricular afterload. Because of this, many patients with aortic stenosis have a better than average function when assessed using conventional echocardiographic parameters, such as ejection of shortening fraction. Myocardial Doppler allows

Figure 18C-31 Myocardial Doppler velocity trace and colour-coded tissue tracking of the left ventricular free wall in a 12-year-old patient with tricuspid atresia and concordant ventriculo-arterial connections who had undergone a Fontan operation at age 3.2 years. Tissue tracking on the left demonstrates no shortening near the apex, and the concomitant myocardial velocity (green) shows almost a flat systolic wave and a positive e-wave, indicating myocardial shortening during diastole at the apex. The ellipse highlights the area of wall motion abnormality.

Figure 18C-32 Blood pool Doppler sampled in the left ventricle immediately below the mitral valve from the same patient as shown in Figure 18C-31, demonstrating abnormal intracardiac flow during systole (white arrows) preceding the flow during diastole.

for a more detailed examination of function, and revealed decreased systolic and diastolic myocardial velocities, as well as strain rate in those patients with aortic stenosis but normal shortening fraction.⁵³ Furthermore, the novel myocardial Doppler methods demonstrate positive effects of relief of stenosis by balloon dilation, and as such are well suited to monitor effects of treatment.⁵⁴

Anomalous origin of the left coronary artery from the pulmonary trunk is a rare but important lesion, as it represents a clinical model of hibernating myocardium. Most patients in whom the left coronary artery can be reimplanted successfully into the aortic root may have a complete recovery of global left ventricular function, with a good long-term outcome.⁵⁵ Myocardial Doppler techniques can beautifully demonstrate the pre-operative dysfunction and the temporal evolution of recovery of myocardial function after reimplantation of the left coronary artery.⁵⁶

Monitoring Ventricular Function in the Intensive Care Unit

The new myocardial Doppler techniques are well suited for application in the intensive care unit, where non-invasive assessment of myocardial function in particular is frequently required following surgical treatment of patients with congenitally malformed hearts. Some of these patients

have poor echocardiographic windows because of artificial ventilation, drainage tubes, and dressings. Thus, an easy echocardiographic method is required, which does not depend on imaging the heart in total, but like isovolumic acceleration needs only to image the left or right ventricular free wall at the level of the atrioventricular valvar annuluses. Singular measurements of isovolumic acceleration can provide a quick overview of ventricular contractile function, but the non-invasive assessment of the force-frequency relation yields more detailed information.^{25,57} Using these techniques revealed a marked variability in response to cardiopulmonary bypass, ranging from no effect in patients undergoing closure of atrial septal defects to a profound reduction in the force-frequency relation after the neonatal arterial switch operation (Fig. 18C-33).

Monitoring the Results of Cardiac Transplantation

In some patients with a failing myocardium, or very complex malformations, cardiac transplantation may be the only therapeutic option. While results of transplantation have become very good, later rejection of the transplanted heart remains a clinical problem. Non-invasive imaging techniques such as echocardiography have previously been used to monitor these patients.⁵⁸ Myocardial Doppler measurements, in particular isovolumic acceleration, are well suited to assess such patients serially.⁵⁹ We have learnt that the transplanted heart has an abnormal systolic and diastolic function, even in the absence of rejection. Thus, reference values from normal hearts cannot be used for comparison.⁶⁰ Using measurements in patients with transplanted hearts during absence of evidence for rejection, and thus using them as their own controls, showed that an acute reduction in isovolumic acceleration may be a sensitive indicator of impending rejection.⁵⁹

Cardiomyopathies

In recent years, novel pharmacological treatments have become available for some patients with cardiomyopathies, which in turn has increased interest in their clinical

monitoring. For those cardiomyopathies that cannot be treated by drugs, such as Duchenne's muscular dystrophy, echocardiography has been used to yield information on prognosis.⁶¹ Likewise, in patients with hypertrophic cardiomyopathy for whom only symptomatic treatment is available, myocardial Doppler can identify prospectively patients with subclinical disease who may later develop the classical hypertrophy. Patients with genetic mutations known to cause hypertrophy who had no echocardiographic signs were examined by myocardial Doppler, and restudied 2 years later.⁶² Those who had manifest disease at the second examination already had reduced myocardial velocities 2 years preceding manifestation of the disease.

For some having cardiomyopathies such as Pompe's and Friedreich's, new recombinant enzyme therapy has recently become available, making the diseases potentially reversible.⁶³ The new myocardial Doppler techniques have been successfully applied to monitor the effect of recombinant enzyme therapy on cardiac function.

Thalassaemia is another potentially reversible cardiomyopathy. Deposition of iron, which may lead to myocardial dysfunction, can be reversed by appropriate chelation therapy. Using myocardial Doppler, abnormalities of mural motion could be detected in those parts of the left ventricle in which deposits of iron were detected by magnetic resonance imaging.⁶⁴ The majority of patients had little or no clinical symptoms and normal shortening fraction on m-mode echocardiography, yet myocardial velocities were abnormally low. This is further proof that myocardial Doppler enables detection of abnormal heart function before it becomes evident clinically.

Leucaemia and other forms of childhood cancer are treated successfully with drugs, albeit potentially cardiotoxic. In many survivors of childhood cancer treated with Adriamycin, conventional m-mode based indexes of cardiac function may be normal at rest, with abnormalities only becoming evident during exercise. Myocardial Doppler-derived measurements present a sensitive tool to detect such abnormal contractile function early, without the need for further exercise testing.⁶⁵

Figure 18C-33 Force frequency curves from patient after (A) closure of an atrial septal defect (ASD) and (B) transposition (TGA) following a neonatal switch operation. Note that, after closure of the atrial septal defect, there is little difference in the curve before and 3 hours following surgery, while in the neonate following the arterial switch operation the curve at 6 hours is flat with almost no increase in isovolumic acceleration (IVA) with increasing heart rate, and is still abnormally low after 24 hours, suggesting depressed contractile function following surgery.

FUTURE DEVELOPMENTS

During contraction and relaxation, the left ventricle performs a complex motion. Evaluating longitudinal and radial function alone cannot fully describe this motion, and thus is insufficient to assess function. The left ventricle also undergoes torsional deformation.⁶⁶ This can be assessed by tagged magnetic resonance imaging. Recently, myocardial Doppler techniques have also been used to assess such left ventricular torsional deformation. The torsional deformation is shown to increase from infancy to adulthood.⁶⁷ Abnormal torsion may be sign of myocardial disease. As the ventricles have a complex shape and motion during contraction and relaxation, information about these movements in three dimensions is desirable. Future developments will be directed towards techniques which enable assessment of cardiac deformation in three dimensions.⁶⁸

Two examples of clinical applications of these new echocardiographic techniques in the long-term follow-up of patients with congenitally malformed hearts.

Magnetic Resonance Imaging and Computed Tomography

LARS GROSSE-WORTMANN, WHAL LEE, and SHI-JOON YOO

Echocardiography remains the most widely used diagnostic imaging modality in the assessment of patients with congenitally malformed hearts, owing to its portability and excellent temporal resolution, and the contrast provided by the interface between the blood and the tissues.¹ Ultrasound, however, does depend on acoustic windows, which are often limited in older patients or following surgery. Both computed tomography and magnetic resonance imaging allow imaging at all angles, and largely irrespective of surrounding structures or air. Consequently, and because they deliver multi-slice or true three-dimensional images, magnetic resonance (Table 18D-1) and computed tomography help clarify the three-dimensional morphology of the cardiovascular system and its topographic relationships to the extracardiac structures, such as the trachea and bronchuses.

The history of magnetic resonance imaging is dotted with Nobel prizes awarded in physics, chemistry, and medicine. In 1946, Felix Bloch² and Edward Purcell³, in the same journal issue but independently of one another, described the behaviour of the nucleuses of certain elements of the periodic system when introduced into a magnetic field. Imaging using magnetic resonance, however, was not possible until Paul Lauterbur applied gradients spatially to encode the signal, producing the first magnetic resonance image of two tubes of water in 1971. This work was published in 1973,⁴ and, in the following year, he published the first images of a living animal, a clam.⁵ When Richard Ernst applied the Fourier transformation to the technique pioneered by Lauterbur, magnetic resonance

imaging, as we know it today, was born.⁶ The first magnetic resonance images of the heart date back to the early 1980s.⁷ Major breakthroughs include electrocardiographic gating in 1984,⁸ phase velocity mapping in the same year to measure the flow of blood,⁹ and gadolinium-enhanced magnetic resonance angiography in 1988.¹⁰

Since then, improvements of the hardware, particularly stronger and faster gradients, as well as higher resolution coils, paralleled by exponential increments in the capacity to process data, have laid the foundation for an array of sequences and applications. Between the early days of cardiovascular magnetic resonance imaging in the 1980s and the present, the technique has undergone an evolution from a non-invasive anatomical tool to a powerful window towards haemodynamics and myocardial mechanics.

The technological advancement in computed tomography is moving towards faster scanning, as well as a reduction in irradiation. Both improvements have helped to establish computed tomography in the work-up of pathology of the vessels and the airways in children. We can now obtain images during spontaneous breathing, and at an acceptable level of exposure to irradiation.

In this section of the chapter devoted to imaging, we offer an overview of the information now provided by magnetic resonance and computed tomography in children with congenital and acquired cardiac disease, discussing the limitations and risks of the techniques. We hope to guide cardiologists in using the appropriate cross sectional modality for imaging their patients, and in understanding the results.

TABLE 18D-1

COMMON INDICATIONS* AT A DEDICATED PAEDIATRIC SERVICE FOR CARDIAC MAGNETIC RESONANCE IMAGING

Post-operative tetralogy of Fallot
Stenosis of the right and left pulmonary arteries
Native and repaired coarctation of the aorta
Aortic valvar insufficiency
Marfan syndrome
Partially anomalous pulmonary venous connection
Functionally univentricular circulations after the bidirectional cavopulmonary connection, or with Fontan-type anatomy
Arrhythmogenic right ventricular cardiomyopathy
Dilated and hypertrophic cardiomyopathy
Cardiac mass
Takayasu's arteritis

*Not given in order of frequency.

MAGNETIC RESONANCE IMAGING

Physical Principle

Magnetic resonance imaging utilises the varying magnetic properties of hydrogen nucleuses, or protons, in different tissues in the body.^{11,12} When excited by a radio-frequency pulse, the protons, like small stab magnets, briefly change orientation before returning to their initial state. During this relaxation, the protons give off energy. This process is termed resonance, or echoing. It can be measured, and then translated mathematically into an image of grey values. The way these echoes are created and manipulated determines the shading of the resulting image, a process termed weighting. Manipulation of the echo can be achieved by applying one or more additional radio-frequency pulses following the initial pulse that change the spin of the protons. This is called spin echo. Another way to influence the echo is by alternating the orientation of the magnetic field of the scanner during proton relaxation, resulting in a gradient echo sequence.

Magnetic resonance imaging operates between the poles of the duration of the scan, its temporal and spatial

resolutions, and the intensity of the signal, or its ratio to the produced noise. As a general rule, improving one of these features typically worsens the other three. The settings used, therefore, have to be composed to maximise the benefit from a particular sequence in each individual patient. A comprehensive approach to the physics is beyond the scope of this chapter, and the interested reader is directed elsewhere.¹¹

Practical Considerations and Patient Safety

Cardiovascular magnetic resonance is a complex modality. Awareness of the underlying physical principles and computations is a prerequisite to its successful application to children, in whom a cookbook approach frequently fails. The field of congenital cardiac disease, on the other hand, bears its own intricacy that must be understood to best design the examination. Training in both aspects of paediatric cardiovascular magnetic resonance is essential to maximise the gain from this technique. An intimate cooperation between radiologists and cardiologists is advocated to master and help advance the fast evolving field.

It is our practice to sedate or anaesthetise most patients younger than 6 years of age. This, however, is only a rule of thumb, and varies according to the maturity of the patient, as well as to anaesthetic support, the monitoring available, and the presence of a physician. Careful preparation and guidance of the child prior to and during the scan have a beneficial effect on the quality of the images obtained. Prior to any study, absolute and relative contraindications must be addressed.^{13,14} Pacemakers and other electronic implants, such as pumps for infusing drugs, are currently absolute contra-indications to magnetic resonance imaging. Controversy surrounds magnetic resonance imaging at 1.5 Tesla following implantation of metallic objects.¹⁵ Patients with non-ferromagnetic foreign bodies can probably undergo testing immediately after implantation. For an implant or device that is weakly ferromagnetic, such as most stents, coils, and artificial valves, it is customary to wait until at least 6 weeks after implantation in order to prevent dislodging.¹⁴ A strong magnetic field can induce an electrical current in temporary or permanent pacing wires, causing thermal injuries to surrounding structures.¹⁶ If they are within or close to the field of view, all objects are desirably not only magnetic resonance imaging safe but also compatible, in order not to impair the information that can be obtained from the study (Fig. 18D-1).¹⁴ If possible, dental braces should be removed. The classification into safe and compatible is currently being replaced by the terminology safe and conditional, introduced by the American Society for Testing and Materials International. According to the new terminology, a patient with an implant labeled conditional may undergo magnetic resonance testing if certain requirements pertaining to the scanner and sequences used are met. Both classifications currently co-exist and can be found on the device packaging. Gadolinium-based contrast mediums are safe, with a risk of anaphylactic reactions in the range of 0.001% to 0.01%.¹⁴ Patients with severe renal insufficiency, expressed by a glomerular filtration rate of less than 30 mL/min/1.73 m², face a risk of developing nephrogenic systemic fibrosis after exposure to gadolinium, and should not receive contrast.¹⁷ Nephrogenic systemic fibrosis was initially observed in, and thought solely to affect, the skin, but internal organs such as liver, lungs, and heart may be involved. An extensive review of the safety aspects

Figure 18D-1 Artifact from a vascular stent in the arterial duct following a hybrid procedure consisting of bilateral banding of the pulmonary arteries and placement of a ductal stent for hypoplastic left heart structures. DAO, descending aorta; LV, left ventricle; PT, pulmonary trunk; RPA, right pulmonary artery; TA, transverse arch.

of magnetic resonance can be found elsewhere.¹⁴ With the exception of real-time imaging and contrast-enhanced angiography, most sequences require electrocardiographic gating to compensate for cardiac motion. Respiratory motion is countered either by breath-holding, tracking the motion of the diaphragm, or acquiring multiple sets of data to average out the effects of the inconsistent position of the thorax.

Techniques for Imaging

Each examination begins with a series of static scout images, or localizers, of the thorax and adjacent body parts in three orthogonal body planes (Fig. 18D-2). With most

Figure 18D-2 Bright blood view of the left ventricular outflow tract in a patient with combined aortic valvar disease. The aortic valve is doming and stenotic, with post-stenotic dilation of the proximal ascending aorta. The turbulent jet causes a characteristic dephasing artifact. AO, aorta; LV, left ventricle.

recent scanners, the scout images with an acceptable spatial resolution can be obtained within 1 or 2 minutes, making most anatomical information readily available. All subsequent sequences for detailed examination are planned using this scout, as well as any subsequently obtained images, as a reference. As a principle of prescription, any imaging plane is defined unequivocally either by three points, so-called three-point planning, or by how it dissects two separate images previously obtained, the so-called double-oblique technique.

Cine Imaging

These moving images of the beating heart are the workhorse of current magnetic resonance imaging in patients with congenitally malformed hearts (Figs. 18D-3 and 18D-4; see also Fig. 18D-2). Blood is signal-intense, and contrasts well with the grey myocardium. Turbulent flow causes loss of signal from dephasing, and can be identified as dark streaks within the bright blood pool (see Fig. 18D-2). As an important difference to echocardiography, these moving images, with few exceptions, are not acquired in real time, but are assembled over many cardiac cycles, so that a temporal correlation of

cardiac events with the coinciding beat-to-beat electrocardiogram is not possible. A representative work flow for cine imaging is shown in Figure 18D-3. The strategies to achieve the basic views vary between users. A stack of 10 to 12 short-axis cine images (see Figs. 18D-3 and 18D-4) are used to calculate ventricular volumes and myocardial masses (see Fig. 18D-4B). As opposed to echocardiography, this method does not rely on geometric assumptions, and is widely accepted as the gold standard tool for ventricular volumetry.

A modification of cine imaging is myocardial tagging (Fig. 18D-5): Here, selective saturation pre-pulses spoil all spins within multiple planes perpendicular to the plane of imaging, thus superimposing a grid of black lines across the field of view. The black lines persist through systole, and are deformed by myocardial contraction. From the degree of deformation, it is possible to calculate radial and circumferential strain, as well as ventricular twisting.¹⁸⁻²¹ The assessment of cardiac function is fuelled by the expectation of better understanding of myocardial mechanics, and by the hope of detecting and treating myocardial disease in its early stages. The sensitivity of analysis of regional

Figure 18D-3 Work flow for anatomical and cine imaging. Each scan plane is prescribed starting from two differently angled reference images, using the double oblique technique, for the four-chamber view in this figure. Following coronal (A), axial (B), and sagittal (C) localizer images, cine imaging begins with a vertical long-axis or pseudo-two-chamber view (D). From here, a set of short-axis imaging planes (E) is prescribed parallel to the atrioventricular groove, using the previously acquired vertical long-axis view and the axial localizer as reference images. A four-chamber view (F) cuts through the mitral and tricuspid valves and through the ventricular apex. If needed, a three-chamber view (H) of the left atrium (LA), left ventricle (LV), and proximal ascending aorta can be obtained by placing the imaging plane through the aortic and mitral valves (AV, MV) in the basal short-axis plane (G). Imaging perpendicular to the three-chamber view opens up the left ventricular outflow tract (I). AO, aorta; PT, pulmonary trunk; RA, right atrium; RV, right ventricle; TV, tricuspid valve.

Figure 18D-4 Stack of short-axis images, parallel to the atrioventricular groove. Contours (A) are drawn around the left ventricular endocardium (red), epicardium (green), and right ventricular endocardium (yellow). This is repeated at end-diastole and end-systole in each slice of the short-axis stack. Using the contours in A, a three-dimensional model (B) is reconstructed. The red contours and green mesh indicate the endocardium and epicardium, respectively, of the left ventricle. The right ventricular endocardium is in yellow. The computer calculates the volumes, ejection fractions, and cardiac output. The mass is typically given only for the left ventricle, as the right ventricular trabeculations preclude accurate measurements.

Figure 18D-5 This 17-year-old boy has myocardial infarction after Kawasaki disease as a toddler. Myocardial tagging is shown in a midventricular short-axis slice at the beginning (A) and end (B) of systole. The tagging lines change from straight to inward convex, following the myocardial motion during contraction (*black arrowheads*). The inferolateral wall of the left ventricle (LV) is akinetic (*white arrowheads*), indicated by the grid lines remaining straight. The black lines are strongest at the beginning of systole and fade during the cardiac cycle. The akinetic wall segment of the left ventricle corresponds to a zone of hyperenhancement late after gadolinium, indicating myocardial infarction (C; *arrowheads*). RV, right ventricle.

wall motion can be increased by protocols inducing stress, using dobutamine or magnetic resonance compatible ergometers.

Measurements of Flow

Phase contrast imaging is another key technique in the assessment of congenitally malformed hearts by magnetic resonance. It is used to quantify the velocity and volumes of flow (Fig. 18D-6).²²⁻²⁴ The ability to assess the flow in all major vessels in any orientation makes this technique ideal for the assessment of congenitally malformed hearts.

Data is acquired during spontaneous breathing or with the patient ventilated, as breath-holding manoeuvres can affect the flow of blood. The vessel is imaged perpendicular to its long axis, so-called through-plane imaging. In Figure 18D-7, we show the prescription of the planes to image the great vessels as well as the atrioventricular valves, using the double oblique technique. Phase contrast sequences produce a cine modulus image (see Fig. 18D-6A) of the anatomy, as well as a velocity-encoded image which contains the information pertaining to flow (see Fig. 18D-6B). Phase contrast imaging is used to

Figure 18D-6 Magnitude (A) and velocity (B) images of a phase contrast study of the ascending aorta in a patient with aortic valvar regurgitation. The resulting curves of flow volume over time (C) show flow reversal in the ascending (area shaded in red) and descending (area shaded in yellow) aorta. Flow in the superior caval vein is shown in blue. In patients without extracardiac shunts, the sum of flow volumes in the superior caval vein (SCV) and in the descending aorta (DAO) are expected to be equal to that in the ascending aorta (AAO) with minor discrepancies for measurement inaccuracy and blood flow into the bronchial and vertebral arteries. PT, pulmonary trunk.

Figure 18D-7 Work flow for phase contrast imaging. The prescribed imaging planes are perpendicular to the three-dimensional course of the vessel as long as they transect the vessels on two separate images. Using the localizer images in three orthogonal planes, the cuts for the ascending aorta (A) at the level of the right pulmonary artery, the inferior caval vein (B) at the diaphragm, and the pulmonary trunk (C) are designed. The plane for the ascending aorta typically transects the descending aorta and superior caval vein in a near-perpendicular fashion. The plane for the descending aorta at the level of the diaphragm includes the inferior caval vein between the liver and the atrium. The right (D) and left (E) pulmonary arteries are prescribed off the ascending aorta phase contrast magnitude image and the coronal and sagittal localizers, respectively. Inflow through the atrioventricular valves (F) is imaged in a plane perpendicular to the atrioventricular groove in a vertical long-axis view at end-systole and an axial localizer image.

quantify valvar regurgitation. Flow can accurately be measured in the right and left pulmonary arteries, as well as in systemic vessels. By subtracting pulmonary arterial influx from venous efflux, the amount of systemic-to-pulmonary arterial collateral flow can be calculated in patients with a functionally univentricular circulation, or in those with obstructed right ventricular outflow tracts.^{25–27} Flow across a patent arterial duct can be directly measured. Intracardiac shunts can be calculated by comparing flows in the ascending aorta and pulmonary trunk.^{28,29} Unlike ultrasound Doppler, phase contrast imaging allows analysis of the pattern of flow in all vessels shown in the field of view, helping clarify timing of flows relative to one another. Certain conditions exhibit characteristic patterns: for example, the configuration of the velocity of flow in patients with pulmonary hypertension (Fig. 18D-8) is characterised by an early systolic peak with decreased maximum velocity; one or more secondary peaks; early cessation of systolic forward

flow, with a nadir arriving before that of the ascending aortic flow; and undulation of velocities during diastole.³⁰ Flow trajectories and turbulence can be assessed by imaging along the vessel or jet of flow, known as in-plane imaging, and, experimentally, it is possible to produce four-dimensional phase contrast imaging (Fig. 18D-9). A number of conditions compound the accuracy of phase contrast magnetic resonance, including insufficient temporal resolution, a too high or too low limit of encoding, as well as non-laminar target flow.²³ Large translational movements of the great arteries through the fixed imaging plane, as well as turbulence and swirling in frequently dilated arterial roots hamper the quantification of regurgitation across arterial valves.^{31,32}

Contrast-enhanced Magnetic Resonance Angiography

Gadolinium-based contrast agents can be used to increase the signal from the blood and reduce the time required to acquire images, thus allowing three-dimensional angiography with a submillimeter spatial resolution (Figs. 18D-10

Figure 18D-8 Time-velocity flow profile in the pulmonary trunk in a patient with primary pulmonary hypertension. See text for details.

Figure 18D-9 Flow streamlines in a normal thoracic aorta, reconstructed from four-dimensional, three-directional phase contrast velocity mapping. (Courtesy of A. Frydrychowicz, Freiburg, Germany.)

Figure 18D-10 Contrast-enhanced magnetic resonance angiography in a patient with severe native coarctation (*asterisk*) of the aorta (AO) and massive collateralisation via the internal mammary, intercostal, and vertebral arteries. IMA, internal mammary artery.

Figure 18D-11 Discordant ventriculo-arterial connections in a patient with transposition after an atrial switch procedure. The trabeculated right ventricle (RV) connects to the aorta (AO; shown in red), and the smooth-walled left ventricle (LV) gives rise to the pulmonary trunk (PT; in blue). The complex venoatrial anatomy including the baffle connecting the superior caval vein (SCV) to the mitral valve, and separating the systemic venous return from the morphological right atrium (asterisk) is clearly shown. (Courtesy of S. Sarikouch, Hannover, Germany.)

to 18D-12; see also Fig. 18D-9). When repeated in short intervals, four-dimensional angiography can be performed, with time added as the fourth dimension to the three-dimensional anatomy. The practical temporal resolution of four-dimensional or time-resolved magnetic resonance angiography for the pulmonary vasculature is between 0.5 and 1.0 seconds, depending on the imaging volume and the spatial resolution. The interpretation of an angiogram should always begin with a careful review of the source data. Image processing can highlight the information contained in

the images, clarify topographic relationships, and facilitate demonstration of the anatomy to cardiologists and surgeons. A three-dimensional data set can be displayed either as a projection or as a volume rendered image (Fig. 18D-13; see also Figs. 18D-10 through 18D-12). Maximum intensity projections (see Figs. 18D-12A and 18D-13A), the most commonly used type of projection, resemble static images from fluoroscopic angiography. To create these images, the computer retains the brightest voxels along a virtual beam of projection. The orientation of this projection, as well as the thickness of the projected slice, is freely adjustable during post-processing. Computationally intensive volume rendered images (see Figs. 18D-10, 18D-11, 18D-12B, and 18D-13B) lend a plastic appearance to the anatomy, optionally including colour and a virtual source of light.

Tissue Characterisation

An array of types of static images are available to visualise changes within the myocardial matrix, and also to characterise cardiac or extracardiac masses. The techniques used for tissue characterisation include late gadolinium enhancement imaging, T2- as well as T1-weighted imaging. Late gadolinium enhancement (Fig. 18D-14) is based on the differences in the uptake and wash-out kinetics of contrast medium between healthy and infarcted or scarred myocardium. Acutely necrotic cells or fibrosis retain gadolinium longer than normal myocardium, thus appearing bright on a T1-weighted gradient echo image obtained 10 to 15 minutes after intravenous injection of gadolinium compound. Late gadolinium enhancement has been identified not only in coronary arterial disease,³³ but also in hypertrophic and dilated cardiomyopathy,³⁴ arrhythmogenic right ventricular cardiomyopathy,^{35,36} sarcoidosis, and storage disorders such as Fabry's disease, and in patients after repair of tetralogy of Fallot.³⁷ It has also proved useful in the diagnosis of fibromas.³⁸

Figure 18D-12 Maximum intensity projection (A) and volume-rendered (B) images of an isolated stenosis (asterisk) at the origin of the left pulmonary artery (LPA). PT, pulmonary trunk; RA, right atrium; RPA, right pulmonary artery; RV, right ventricle.

Figure 18D-13 Maximum intensity projection (A) and volume-rendered reformatting (B) of a three-dimensional magnetic resonance angiography in a patient with anomalous connection of the right upper and middle pulmonary veins to the superior caval vein (SCV). AO, aorta; ICV, inferior caval vein; PT, pulmonary trunk; RA, right atrium; RUPV, right upper pulmonary vein; RMPV, right middle pulmonary vein; RV, right ventricle.

Figure 18D-14 Late enhancement imaging 10 minutes after the administration of gadolinium in a patient with right anterior myocardial infarction. The right coronary artery was severed during surgical repair of the aortic valve that had been eroded by infective endocarditis. The signal of the myocardium is nulled, whereas the anterior free wall of the right ventricle (RV) and the inferior ventricular septum are bright, indicating infarcted myocardium and scarring (asterisks). LV, left ventricle.

Figure 18D-15 T2-weighted image in a short-axis orientation at midventricular level in a patient 6 years after heart transplantation. The right ventricular myocardium is thickened and more signal-intense (arrowheads) than that of the left ventricle (LV), consistent with graft rejection. The anterolateral papillary muscle of the mitral valve (asterisk) is also bright. Endomyocardial biopsy one day earlier confirmed acute graft rejection. RV, right ventricle.

T2-weighted spin echo images (Fig. 18D-15) have been used to demonstrate tissue oedema based on the fact that increased amounts of free water protons give off more T2 signal than those found in normal myocardium. As myocardial oedema is found as a result of acute inflammation in myocarditis, T2-weighted imaging helps differentiate it from chronic dilated cardiomyopathy.³⁹ Rhabdomyomas tend to

be brighter than fibromas on T2-weighted images.^{38,40} A high T2 signal is a marker of acute rejection of transplanted hearts (see Fig. 18D-15).⁴¹ T2* and T2 relaxation times correlate with overload of iron in patients with thalassaemia and are increasingly being used to guide chelation therapy.^{42,43}

Fatty infiltration is a pathognomonic finding in studies of autopsied individuals with arrhythmogenic right

ventricular cardiomyopathy.⁴⁴ Using a T1-weighted sequence following pre-pulses to extinguish the signal of the blood for better contrast, fat deposits in the dysplastic myocardium can be visualised experimentally as regions with high intensity of the signal, aiding in the diagnosis during life. In addition, lipomas and, occasionally, teratomas, also appear signal-intense on fat-sensitive sequences.

Imaging of the Coronary Arteries

Aneurysms of the coronary arteries may complicate Kawasaki disease. Abnormalities in origin and branching of the coronary arteries are not uncommonly found in the setting of abnormal ventriculo-arterial connections. An anomalous origin of the main stem of the left coronary artery, or its anterior interventricular branch, with an interarterial or intramyocardial course, must be ruled out in anyone with signs and symptoms of myocardial ischaemia. Imaging the coronary arteries is challenging because of their small size, tortuous course, and the extensive motion of the atrioventricular groove throughout the cardiac cycle. Non-contrast whole-heart magnetic resonance angiography (Fig. 18D-16)^{45,46} uses both respiratory tracking and cardiac gating. Data is acquired only during a period of the cardiac cycle when the chamber size is relatively constant, usually diastasis, and when the diaphragm is at a defined position. Obtaining high resolution images only when the previously identified position of the heart and diaphragm coincide leads to a long scan time of, on average, 8 to 12 minutes. The three-dimensional data set can be reformatted as described above

Figure 18D-16 This three-dimensional data set of the whole heart was acquired in 9 minutes without contrast, using a three-dimensional steady-state free precession technique. The left coronary artery system has a normal origin and branching patterns. There is no aneurysm and no obvious narrowing. However, stenoses cannot be ruled out with certainty. AO, aorta; Cx, circumflex artery; LAD, left anterior descending artery; LV, left ventricle; RV, right ventricle; RVOT, right ventricular outflow tract; SCV, superior caval vein.

Figure 18D-17 In this T1-weighted coronal image of the thorax, the airways, lungs, as well as the vessels are shown in black. The relationships of the trachea and bronchuses to the branch pulmonary arteries and aortic arch are shown. AO, aorta; LPA, left pulmonary artery; Tr, trachea.

for contrast-enhanced magnetic resonance angiography (see Fig. 18D-16). Currently, however, magnetic resonance cannot rule out coronary arterial stenosis with certainty in children.

Imaging the Airways

Magnetic resonance is suitable for depicting the tracheo-bronchial structures in their topographic relationship to the anomalous vascular structures in various anomalies involving the aortic arches, and in the syndrome of the pulmonary arterial sling. Air contains no signal, and the lumen of airways is shown in black in all clinically used sequences (Fig. 18D-17). Spin echo sequences are the techniques most often used for the display of tracheobronchial anatomy.⁴⁷ Cine imaging can provide useful information regarding dynamic compression of the airways throughout the cardiac cycle. Fast gradient refocused echo sequences acquire a three-dimensional data set of the entire thorax to measure lung volumes in a single breath hold. Computed tomography should be performed, nonetheless, in most patients in whom the airway is the primary object of the investigation.

COMPUTED TOMOGRAPHY

Recent Developments in Technology

The basic elements of a computed tomography scanner are the X-ray tube or tubes, and the detectors, which are housed in a gantry. The gantry spins rapidly around the patient while the tube generates X-rays, and the detectors measure the remaining irradiation after penetration of the body. The measured data is then processed to create images using a mathematical algorithm called back projection.⁴⁸ In the first two and half decades after its first clinical use in 1974, the scanners were axial scanners, and the gantry made a complete rotation to acquire an image of a slice, after which the table was advanced by an increment

equal to the thickness of the slice for the next rotation, and so forth.⁴⁹ This conventional step-and-shoot technique needed a long time because of the inter-scan delays between the slices. In the late 1980s and early 1990s, spiral, or helical, scanners were introduced.⁵⁰ With this innovative technology, the gantry rotates continuously, while the table is moved at a constant speed such that the X-rays are beamed in a spiral manner to the patient. This technique allows fast and continuous acquisition of a complete set of volume data. The spiral data is then interpolated to generate axial images.⁵¹ The speed of the scan in spiral scanning enables the complete data set to be acquired within a single breath hold. In 1998, multi-detector technology with four detector rows once again revolutionised spiral imaging technique, allowing acquisition of four imaging slices at a time with a single rotation of the gantry.⁵² Since then, the number of rows of detectors has ever increased, reaching 320 in 2008.⁵³ Multi-detector scanners allow further improvement of the speed of scanning, and coverage of a larger volume. With a slice thickness of 0.5 mm, a single rotation of a gantry with 320 detectors covers 16 cm of the body along the z-axis. The time of rotation of the gantry is below 500 msec in most modern scanners, with the fastest rotation at 330 msec. Another innovation has been the dual-source technology, in which two sets of X-ray tubes and detectors are arranged at a right angle to each other in a gantry.⁵⁴ Dual sources increase the temporal resolution by halving the rotational travel of the gantry needed to acquire a complete image, thus allowing coverage of the whole heart without the use of medication to lower the heart rate, as well as permitting capture of the heart at any chosen time during the cardiac cycle. Coronary arterial imaging requires electrocardiographically gated scanning, in which motion artifact from cardiac pulsation is minimised by

acquisition of data only during the diastolic period of the diastole, or at end-systole. Electrocardiographically gated scans have been of limited use in children because of the high doses of irradiation, but the prospective trigger gating technique now available drastically helps reduce the dose.⁵⁵

Radiation Hazard and Reducing the Dose of Irradiation

There is a linear relationship between the excess risk of cancer and exposure to irradiation, without a threshold even in the low range of 5 to 100 milli-Sievert.^{56–59} Exposure to irradiation in childhood appears to be more harmful than later in life.⁶⁰ Therefore, the prime strategy of avoiding radiation hazard is not to perform computed tomography whenever the information can be obtained with other imaging modalities that do not use irradiation. When it is obvious that computed tomography is the best option, the medical history and the available imaging findings should be carefully reviewed so that the purpose of the study is clearly defined, and scanning can be restricted to the region of interest. Routine coverage of the whole thorax simply because computed tomography is requested is obsolete (Fig. 18D-18). Pursuing quality of images without consideration of the amount of irradiation will lead to excess exposure. The state-of-the-art strategy in computed tomography is not to produce beautiful images, but to produce images of diagnostic quality with the lowest possible doses of irradiation.⁶⁰ The quality of the images tends to be better than what is required for confident diagnosis and decision making. In general, the milliamperage of the current in the tube should be the lowest possible with which quality is maintained. It has been shown

Figure 18D-18 A, This computed tomography was performed at an outside institution for suspected vascular pathology in a neonate. The coverage extends from the head to the abdomen, exposing the patient to an unnecessarily high amount of irradiation. The diagnosis in this case was double aortic arch (not shown). B, This investigation in a 2-year-old boy with complex coarctation of the aorta (*asterisk*) focused on the area of interest. It includes the aortic arch and not the intracardiac anatomy that was elucidated echocardiographically. The radiation dose was less than 0.5 milli-Sievert for this scan. AO, aorta; RPA, right pulmonary artery; SCV, superior caval vein.

that low settings of kilovoltage lead to marked reductions of the dose without sacrificing quality, especially in children.⁵⁷ In addition, the kilovoltage and current should be adjusted according to the size of the target vessels. When imaging large vessels, such as the aortic arch, a lower current can be used. If the target vessel is small, such as diminutive aortopulmonary collateral arteries, a higher current is required for proper delineation of these small structures from the background noise. The dose can be further reduced by automatic modulation, where the current is adjusted according to the thickness and density of the tissues to maintain a constant level of noise.⁶¹ Using recent technologies, it is possible to reduce the dose in paediatric cardiovascular computed tomography to as low as less than one milli-Sievert.^{62,63} Compared to other X-ray modalities, such as frontal and lateral chest radiographs, which produce about 0.1 milli-Sievert, conventional catheterisation with angiography and radioisotope studies, both using 5 to 20 milli-Sievert, or the average natural background irradiation per year, at approximately 2 to 3 milli-Sievert, the dose of computed tomography with the proper low protocol appears acceptable.^{64–66} Whenever radiosensitive tissues such as breast and thyroid are within the exposed area, they should be shielded. A bismuth shield reduces the dose to the breast by approximately two-fifths.⁶⁷

Practical Considerations and Safety

There is no absolute contraindication for computed tomography except for a history of anaphylactic reaction to the iodine-containing contrast medium. As the time of scanning is typically less than 5 to 7 seconds, sedation or general anesthesia is rarely needed.

Vascular enhancement is usually adequate with an intravenous injection of 2 milliliters of contrast medium per kilogram of body weight, followed by a saline chaser. The rate of injection and the trigger delay after the start of injection is adjusted according to the vessels of interest and to the presence of intra- and extracardiac shunts.

Risks and side effects of contrast media are renal impairment as well as allergic reactions. In patients with renal dysfunction the dose should be reduced, or an alternative test should be sought.^{68–70}

Clinical Applications and Choosing the Right Imaging Tool

Because computed tomography involves ionizing irradiation, preference should be given to magnetic resonance imaging whenever possible. Computed tomography can become the first line cross sectional imaging modality in some situations.

One of the major advantages of computed tomography over magnetic resonance imaging lies within the rapid evaluation of the airways and lung parenchyma (Fig. 18D-19; see also Fig. 18D-18). For example, computed tomography is indicated in patients with a cardiovascular malformation that results in compression of the airways, such as vascular rings, pulmonary arterial sling (see Fig. 18D-19), or absent pulmonary valve syndrome (Fig. 18D-20).⁷¹

The spatial resolution, and contrast between blood and soft tissue, provided by computed tomography are superior

Figure 18D-19 The image is from a 5-year-old child with pulmonary arterial sling syndrome. Volume-rendered reconstruction of a computed tomography of the vascular and central airway anatomy demonstrates the origin of the left pulmonary artery (LPA) from the right pulmonary artery (RPA) and its course around the trachea. The trachea is compressed by the vascular sling (asterisk), but also diffusely narrowed (arrowheads). AO, aorta; SCV, superior caval vein.

to that of magnetic resonance imaging.⁷² The evaluation of small and tortuous vessels, such as major aortopulmonary collateral arteries, therefore, or anomalous pulmonary venous channels, is easier with computed tomography (Figs. 18D-21 and 18D-22). Post-operative complications, including mediastinal haematomas, seromas, and vascular aneurysms, are readily identified with this test. Computed tomography is the most sensitive modality for the detection of calcifications in the cardiac valves, myocardium, and stents. It is able to visualise the inside of most models of stents, which is a blind spot in magnetic resonance imaging.⁷¹ Owing to the speed of acquisition, general anesthesia or sedation is rarely needed, even in small infants. Unlike magnetic resonance imaging, computed tomography can be safely performed in patients with pacemakers and other metallic or electronic implants.^{73,74}

FUTURE PERSPECTIVES

High-field magnets of 3 Tesla hold the promise of higher signal-to-noise ratio, higher temporal and spatial resolutions, and shorter scan times, making them especially appealing for cardiac applications in children. The problem of artifacts from field inhomogeneity at higher field strengths, however, has yet to be overcome, and the effects of peripheral nerve stimulation and body core heating must be carefully observed.

Combined imaging units set the stage for tying together the loose ends of haemodynamic measurements during cardiac catheterisation and in the magnetic resonance scanner.^{75–77} Cardiac intervention guided by magnetic resonance imaging has become a reality in

Figure 18D-20 Contrast-enhanced computed tomography angiogram in a 2-week-old patient with absent pulmonary valve syndrome. In the maximum intensity projection image (A), the pulmonary trunk (PT) and its branches are seen to be grossly dilated. The left main bronchus (*asterisk*) is compressed between the left pulmonary artery (LPA) and the descending aorta (DAO). This three-dimensional topographic relationship is shown more clearly in the volume-rendered reconstruction (*arrowheads along the left bronchus in B*). The volume-rendered image of the airways and lung (C) demonstrates the stenotic segment of the left main bronchus (*asterisk*). The left lung is hyperinflated (*arrowheads*). The defect in the medial and upper aspect of the left lung is due to compression of the bronchus by the dilated left pulmonary artery. AAO, ascending aorta; RPA, right pulmonary artery.

selected centers, equipped with hybrid units that incorporate both modalities. The strategies employed range from fusion of images to performing manoeuvres of the catheter and interventions guided solely by magnetic resonance imaging.

Fetal echocardiography has had a great impact on the spectrum of neonatal congenital cardiac disease that we see today. Fetal magnetic resonance imaging (Fig. 18D-23) is feasible using either very fast non-gated sequences or

pseudo-gating, in which a pulsed external signal at a frequency identical to the fetal heart rate is fed into the scanner, thus allowing gated acquisitions (see Fig. 18D-23A).

Currently available contrast mediums are rapidly eliminated in the kidneys and distributed in tissues throughout the body, including the myocardium. So-called intravascular contrast agents are expected to allow acquisition of high spatial resolution three-dimensional angiographies of the arteries and veins.

Figure 18D-21 Computed tomography in a 6-month-old patient with tetralogy of Fallot, pulmonary atresia, and major aortopulmonary collaterals. This reformatted image depicts a large direct collateral artery (*asterisk*) arising from the descending aorta (DAO) and connecting to the descending branch of the left pulmonary artery (LPA). AAO, ascending aorta; PT, pulmonary trunk; RPA, right pulmonary artery; SCV, superior caval vein.

Figure 18D-22 The image shows unrepaired supracardiac totally anomalous pulmonary venous connection with a vertical vein to the left brachiocephalic vein in a 1-week-old neonate. The left upper pulmonary vein is not shown. LLPV, left lower pulmonary vein; PT, pulmonary trunk; RLPV, right lower pulmonary vein; RUPV, right upper pulmonary vein; SCV, superior caval vein.

Figure 18D-23 This patient was found to have a tumour within the left ventricular mass by prenatal echocardiography. With rhabdomyoma and tuberous sclerosis as part of the differential diagnosis, a fetal magnetic resonance scan was ordered to assess for lesions of the brain and kidneys. **A**, A cardiac investigation during the same test showed the mass (*asterisk*). **B**, A postnatal scan 10 days later was conducted to assess the tissue characteristics of the tumour, as well as the ability of the left ventricle (LV) to sustain the systemic circulation. The tumour (*asterisk*) obliterates most of the left ventricle, but sufficient space for the inflow and outflow tracts was preserved (not shown). The left ventricular cavity volume was 37 mL/m² of body surface area. The patient is maintaining a biventricular circulation. AO, aorta; A, right atrium; RV, right ventricle.

Kim and colleagues assessed the quality and usefulness of computed tomography in the evaluation of compression of the airways in 49 patients, three-fifths of whom were neonates with congenitally malformed hearts. The recent development of multi-detector computed tomography can further reduce artifacts produced by motion, and the doses of irradiation, features which are not addressed in this earlier article.

Electrophysiology, Pacing, and Devices

ELIZABETH A. STEPHENSON and ANDREW M. DAVIS

Electrophysiology is a rapidly growing and evolving discipline within both paediatric and adult cardiology. Although there is overlap in the knowledge base of the paediatric and adult electrophysiologist, there are many issues that are unique to young patients and those with congenital heart disease. The knowledge and practise of paediatric electrophysiology now requires extended training and specialised facilities. An on-site paediatric electrophysiology service has now become an essential component of major paediatric cardiac centres.

This chapter presents an overview of paediatric electrophysiology for the general paediatric cardiologist or trainee, incorporating aspects of diagnosis and treatment. Extensive references should allow the interested reader to explore topics at greater depth.

ELECTROPHYSIOLOGY AND CATHETER ABLATION

Diagnosis and Documentation of Tachycardia

When a patient presents with a tachycardia that is documented on a 12-lead electrocardiogram and with a rhythm strip, it is often straightforward to establish the diagnosis and plan the treatment. Occasionally, the diagnosis remains unclear and then the response to vagal manoeuvres or medications will often help to clarify it. Intravenous adenosine is a potent but transient inhibitor of the atrioventricular node, with lesser and variable effects on ectopic atrial or ventricular substrates. It is important to record the electrocardiogram during vagal manoeuvres or the administration of adenosine, as transient and subtle effects can be missed when observing a monitor screen. If it is still not possible to define the arrhythmia mechanism, an electrophysiological study may then be useful in establishing the diagnosis.

Suspected Arrhythmia or Unexplained Symptoms

When a patient has symptoms such as palpitations, dizzy spells, or syncope, but the rhythm is not documented, management may be less straightforward. It is always preferable to document the clinical arrhythmia, prior to undertaking a diagnostic electrophysiological study as non-clinical arrhythmias may be induced during electrophysiological testing. An aggressive protocol of stimulation, for example, those using stimulation with short coupling intervals or including an isoprenaline challenge, can produce arrhythmias in normal subjects, although these are often not

sustained or specific.^{1,2} Nevertheless, if an arrhythmia that does not mimic the clinical one is induced, management based on this finding may be inappropriate. Good examples are the use of antiarrhythmic medication or implantable defibrillators for induced ventricular arrhythmias without clinical correlation, or inappropriate ablation for dual atrioventricular nodal pathways with a risk of producing complete heart block. In adolescents and adults in whom electrophysiological studies can be performed with minimal sedation, it is possible to ask the patient during the procedure whether the symptoms produced by an induced arrhythmia are similar to those noticed clinically. In younger children deep sedation or general anaesthesia is often used, and thus this opportunity is not available. A recording of an arrhythmia can frequently be obtained by using the methods described below, but occasionally electrophysiological studies are necessary for better elucidation of arrhythmias that prove to be elusive.

Methods of Recording an Arrhythmia

- Documentation by paramedics or rapid presentation to an emergency department for an electrocardiogram when an infrequent arrhythmia starts. It is helpful to supply the parent with a letter stating the need for an urgent electrocardiogram and rhythm strip without waiting for triage, as arrhythmias often revert to sinus rhythm while a patient is waiting in the emergency department queue.
- Ambulatory electrocardiography (Holter monitoring) is useful to document the maximum and minimum heart rates seen during normal daytime and sleep and the presence of arrhythmias, as well as the effects of medication. In some, the patient will have a clinical arrhythmia, or short-lived asymptomatic arrhythmias, while wearing the monitor. Diagnostic clues such as intermittent pre-excitation may be documented. Repeating the test on 2 or 3 consecutive days may increase the diagnostic yield, but this is often an unrewarding investigation when symptoms are infrequent.
- Exercise electrocardiography will document the heart rate response during exercise, the exercise tolerance, and presence of ischaemia. When symptoms are related to exercise, this may also provoke the arrhythmia. Exercise tests need to be tailored to younger children who find adult protocols to be too slow and uninteresting. It is important to perform maximum, or symptom-limited, tests rather than automatically stopping the test when a preconceived maximum heart rate is achieved, as is commonly performed in adults. In addition to an exercise test based on a protocol, a shorter test in which

the treadmill is advanced manually to maximum speed over 1 minute and then to maximum elevation over 1 minute (sprint test) can be used to try to reproduce a rapid peak exercise response. Arrhythmias sensitive to catecholamines may occasionally be provoked by such a peak exercise test following a negative test based on a less aggressive protocol.

- Tilt testing is occasionally useful in establishing the cause of syncope, particularly when the symptoms are suggestive of neurally mediated (vasovagal) syncope.³ However, the test is unpleasant for the patient, and the sensitivity and specificity of this test are mediocre, with a high rate of false positives and false negatives, and this must be taken into account when interpreting the results.³⁻⁸
- Event recorders are perhaps the most effective method of documenting infrequent and short-lived arrhythmias, particularly when the symptoms are vague or multiple. The patient is supplied with a small recorder that allows an electrocardiogram to be recorded when symptoms occur. Usually the recording is transmitted telephonically to a base station and then analysed. The patient can record symptoms during normal daily activities, send in any number of recordings, and keep the recorder for an extended period. There are two different types: pocket or loop monitors. The pocket monitors are carried close to the person in a pocket or handbag, and applied to the chest when the patient is symptomatic. The continuous loop recorders are of a similar size but remain attached to the chest via leads and retain a 1- to 5-minute recording that is continuously updated in memory. When a symptom occurs, the recorder is activated manually by the patient or parent and stores information from immediately before and for a programmed period after activation. The continuous recordings are more useful, albeit that constant wearing of the electrodes may cause skin irritation. Compliance can also be an issue, as it is inconvenient to reapply the monitor every day, and adolescents will frequently be quite self-conscious about wearing the monitor. Advantages include knowledge of where the device is at all times, and the ability to make recordings that include the onset of symptoms. It is also ideal for confirming symptoms caused by simple extrasystoles or other short-duration arrhythmias. Both types of recorders are also useful for confirming that symptoms, often transient and unusual, are not arrhythmic, as when numerous recordings of sinus rhythm are sent in.
- Implantable recorders are occasionally useful when recordings during the symptoms remain elusive.⁹ These devices, similar in size to a small pack of chewing gum, are implanted under the skin of the chest and activated by an external unit carried by the patient when a symptom occurs. They will also automatically record any rhythms that fall outside of preset normal parameters. The recording is downloaded thereafter by telemetry, similar to pacemaker interrogation. They can function for a year or longer, until the battery is exhausted. This method is usually reserved for patients with negative non-invasive studies and continued concern about symptoms. They are particularly useful for syncope that prevents the patient from using an event recorder and for very infrequent symptoms. The invasiveness of

these recorders makes them inappropriate for benign symptoms.

Life-threatening Arrhythmias

When a patient presents with an out-of-hospital cardiac arrest or a presyncopal tachycardia that reverts before diagnosis, then it is no longer safe merely to await a spontaneous recurrence to document the rhythm, and invasive electrophysiology studies may be required. In this setting, it is more likely that any arrhythmias that are found will be clinically relevant and merit appropriate treatment.

Evaluation of Effectiveness and Safety of Drug Treatment

A major early role for electrophysiological studies was to establish which medication was effective for treating an arrhythmia. This was a particularly prominent indication in adults with ventricular tachycardia and after repair of tetralogy of Fallot and in children with supraventricular tachycardia resistant to usual therapies.¹⁰⁻¹⁴ Currently, there is a minimal role for such testing either for anti-arrhythmic or pro-arrhythmic effects¹⁵⁻¹⁷ of drugs.

Ventricular Stimulation Testing

In adults with left ventricular dysfunction, or after myocardial infarction, electrophysiological studies have been used for assessment of the risk of sudden death. When ventricular arrhythmias are non-inducible, or become so with anti-arrhythmic medication, the prognosis may be better. Left ventricular dysfunction, however, is a powerful predictor in its own right, and in many such patients, it is not possible to find a drug that renders the arrhythmia non-inducible. While empirical treatment with amiodarone, despite leaving patients inducible, has been found in some studies to improve the prognosis, this is not a uniform finding and the trend is to use an automatic implantable cardioverter defibrillator.¹⁸⁻²⁴ The landmark sudden cardiac death in heart failure trial (SCD-HFT) showed no survival benefit in adults from the use of amiodarone as a primary prevention measure; in contrast, the implantable defibrillator conferred a 23% reduction in mortality.²⁵ In patients with dilated cardiomyopathy, clinical sustained monomorphic ventricular tachycardia can often be reproduced during electrophysiology study. It is important to exclude bundle branch re-entry in these patients as this arrhythmia is amenable to ablation. If the dilated cardiomyopathy patient has non-sustained ventricular tachycardia, or has presented with syncope, invasive electrophysiology study is, however, of no additional benefit in risk stratification.^{26,27} While there is minimal data available, some survivors of congenital cardiac surgery with ventricular dysfunction, ventricular arrhythmias on ambulatory monitoring, or inducible arrhythmias at electrophysiological study, receive drug treatment and/or implantable defibrillators.^{28,29}

Alternative approaches to ambulatory monitoring and electrophysiological studies include assessment of heart rate variability over 24 hours, as a potential predictor of sudden death. Low heart rate variability suggests a worse prognosis in adult patients with left ventricular dysfunction or after myocardial infarction, and these patients may receive

antiarrhythmic treatment or undergo implantation of a defibrillator.³⁰ Whether it is appropriate to extrapolate this data to patients with congenital heart disease is not clear. There are significant differences related to age as well as acute effects from surgery, but few systematic studies.^{31,32} Signal-averaged recordings evaluated for late ventricular potentials have also been found to be a marker of a poor prognosis in adults, and are used in the diagnosis of diffuse myocardial disease such as arrhythmogenic right ventricular dysplasia.³³ Again, even though normative data for children has been published,³⁴ there are few studies in children with congenital heart disease, and none as yet has demonstrated a useful role in this particular population.^{35,36} (This is explored further under ventricular tachycardia, later in this chapter). Specialised exercise testing for microvolt T-wave alternans offers another non-invasive approach. In general this testing has a good negative predictive value and thus testing may be helpful in the risk stratification process. Normative data for children has been published but more paediatric follow-up data is needed.³⁷⁻³⁹

Evaluation of the Conduction System

Historically, invasive electrophysiology studies were used to document the level of atrioventricular block in patients with conduction system disease: block above and below the bundle of His being associated with a better and worse prognosis, respectively. Pacemaker indications are outlined in the pacing section of this chapter and no longer rely on electrophysiology study.^{40,41}

Interventional Management

Overdrive pacing and programmed stimulation can be used to terminate acute arrhythmias without the need for antiarrhythmic medication or electrical cardioversion. This technique is ideal when there are already pacing leads in place, such as temporary epicardial leads after cardiac surgery or when a permanent pacemaker has been implanted. In patients with malignant recurrent arrhythmias, and/or when medication is ineffective, temporary intracardiac electrodes could be placed to avoid repeated cardioversion until a more long-term strategy is determined. A transoesophageal electrode can be used in diagnosis of arrhythmias with cryptic atrial activity on surface tracings. It can also be used to terminate atrioventricular re-entry tachycardias and atrial flutter.⁴²

When antiarrhythmic medication is ineffective, poorly tolerated, or causes side effects in patients with chronic arrhythmias, then more aggressive management is required and electrophysiological testing may be performed to define the substrate for the arrhythmia and to plan treatment. Tachycardia that is reliably terminated with pace-stimulation but not amenable to ablation can be managed by implanting an anti-tachycardia pacemaker. If anti-tachycardia pacing accelerates the arrhythmia, or produces other arrhythmias, an implantable cardioverter defibrillator may be indicated. Antiarrhythmic surgery has been previously used to cure arrhythmias through excision or cryoablation of ectopic foci or accessory pathways.⁴³⁻⁴⁶ Prior electrophysiological testing was usually required to confirm the anatomy of the substrate and to avoid prolonged intra-operative electrophysiological mapping. Antiarrhythmic surgery laid the foundation for transcatheter ablation therapy but is now rarely indicated for most common arrhythmias. Nonetheless, antiarrhythmic surgery is still performed, often combined with

other cardiac surgery, especially Fontan revision,^{47,48} and pulmonary valve replacement in patients late after repair of tetralogy of Fallot. Currently, radio-frequency ablation or cryoablation is the most common reason for undertaking an electrophysiological study in children.

RADIO-FREQUENCY ABLATION AND CRYOABLATION

Transcatheter ablation was first observed serendipitously when a patient undergoing an electrophysiological study required defibrillation. The energy from the defibrillator accidentally passed down the electrode recording from the His bundle and created complete heart block.⁴⁹ Subsequent animal studies confirmed that complete heart block could be reliably created using this technique. His bundle ablation using direct current became a useful treatment for patients with atrial arrhythmias refractory to medical therapies, especially atrial fibrillation, but it required implantation of a permanent pacemaker.^{50,51} Side effects from the high energy that was required included barotrauma with ventricular dysfunction. Cardiac rupture was also described when ablation was attempted in the coronary sinus to ablate accessory pathways.^{52,53} Alternative energy sources used, historically, with some success included low-energy direct current ablation, direct laser energy and indirect laser heating of the catheter tip.⁵⁴⁻⁵⁶

The development of radio-frequency energy as a tool for ablation was enhanced with the development of steerable electrode catheters so that discrete controlled amounts of energy could be delivered accurately to the target while avoiding damage to other structures.^{57,58} Delivery of energy is gradual and steady, rather than the explosive instantaneous delivery produced by direct current ablation, and it can be applied repeatedly until effective. Unlike direct current ablation, which caused skeletal muscle contraction and pain, radio-frequency ablation is relatively painless and can be performed under local anaesthesia. While catheter ablation was initially developed to create complete heart block, this is seldom required in children, in whom radio-frequency ablation is usually used to affect a direct cure of a range of arrhythmias (Fig. 19-1).

More recently, catheter based interventions using cryoablation have become more widely used.^{59,60} Using this technique, localisation of the region of interest is performed in a manner similar to radio-frequency ablations. Testing of these sites is then performed by extreme cooling, rather than heating, of the catheter tip. This temporarily inhibits tissue function (loss of pathway activity or loss of dual atrioventricular node behaviour, for example). When an appropriate site for ablation is located, the cryothermal energy is increased, freezing the tissue with a typical application time of 4 minutes, creating a permanent lesion. The typical mapping temperature is -30°C and the typical ablation temperature is -70 to -75°C . This technique offers the advantage of potentially reversible lesions, thus reducing the risk of permanent heart block or other undesirable tissue effects. It also offers less painful application of energy, but may be complicated by slightly higher recurrence rates.^{61,62} As this remains a fairly new technology, it remains to be seen what the long-term efficacy will be, particularly once the learning curve has been completed. Many laboratories now have both radio-frequency and cryoablation available, and tailor the usage of each to the individual patient.

Figure 19-1 Catheter electrodes used for electrophysiology and ablation: (a) ablation catheter; (b) 6 French decapolar electrode catheter; (c) 6 French quadripolar electrode catheter, also available in 5 French; (d) 6 French bipolar electrode catheter; (e) 2 French quadripolar catheter; (f) 8 French Halo catheter; (g) basket electrode catheter.

Tissue Effects of Radio-frequency Energy

During delivery of radio-frequency energy, the tissue in contact with the ablation catheter is heated.⁶³ At temperatures of 50°C and greater, there is permanent denaturation of the cell membranes and tissue dehydration. After further heating, there is coagulation necrosis of the tissue with surrounding haemorrhage and inflammation. The lesion retracts acutely because of dehydration, and the coagulation necrosis heals to form a well-demarcated fibrotic scar. The size of the lesion depends on the power of the radio-frequency energy delivered, the size of the ablation catheter, the duration of heating and the temperature achieved.^{64–66} Small electrode tips result in a rapid rise in temperature with boiling at the tissue interface and charring of blood, with a rise in impedance, a decrease in heat transfer and a smaller lesion. Longer electrode tips, with less contact with tissue, have a reduced current density so that the temperature rise is curtailed. This allows use of higher powers and a longer delivery of energy without boiling and charring, and it creates deeper lesions. A standard 7 French ablation catheter with a 4-mm tip will produce lesions 5 to 6 mm in diameter and 2 to 3 mm deep. After delivery of energy is discontinued, the tissue in contact with the electrode is hotter than the surrounding tissues and continued heat transfer occurs. This thermal latency explains why lesions can continue to increase in size after cessation of delivery of energy.⁶⁷ Catheters with cooled tips allow the use of even greater power without charring and create even deeper lesions.⁶⁸ Scar tissue takes longer to heat

and produces smaller lesions, thus making lesion creation in scarred regions challenging.⁶⁹

During the healing phase, tissue on the border of the lesion may recover if permanent denaturation was not achieved. Progressive necrosis may also occur at the border of a lesion if sufficient inflammation and microvascular damage occurred during delivery of energy.^{63,70,71} Therefore, it is possible for an acutely successfully ablated arrhythmia to recur, or a partially successful ablation to become completed. The latter progression is seen less often clinically. In neonatal lambs, delivery of radio-frequency energy resulted in a progressive increase in the size of lesions in the atrial and ventricular myocardium, but not in the atrioventricular groove.⁷²

Procedure

Radio-frequency and Cryoablation Equipment

Radio-frequency ablation is performed using a dedicated alternating current generator coupled to an ablation catheter and an indifferent plate attached to the back of the patient. The catheters are typically 5 to 7 French, have bipolar or quadripolar tips that can be deflected, and have a steering mechanism to facilitate positioning at the appropriate site. Radio-frequency energy is delivered at cycle lengths of 300 to 750 kHz. During delivery of energy, the rhythm, temperature, and impedance at the tip of the catheter are closely monitored.

Temperatures of 60° to 70°C are required for effective ablation, while temperatures below 50°C often result in a transient effect with later recovery of conduction. Much higher temperatures can result in charring of blood at the tip of the catheter, which insulates the tip from the tissue and prevents effective heating of the tissue. Feedback control from the thermistor at the tip of the catheter to the generator is used now to limit the power, to control the rise in temperature, and to avoid excessive temperatures.^{73,74}

Cryoablation can be performed with either 7 French, 6-mm tip, or 9 French, 8-mm tip, cryothermal catheters. It requires a dedicated cryoablation console. The temperature is lowered to –30°C for 60 seconds and testing can be performed to determine appropriateness of that site (cryomapping). A useful feature is the fact that the catheter adheres to the application site. Once a promising ablation site has been identified, the temperature will be decreased to –70°C for 4 minutes to complete the ablation. It is important to continuously monitor the rhythm during energy application as lesion expansion can be seen during cryoablation, even when not seen during cryomapping.⁷⁵ In some laboratories cryoablation may be performed without previous cryomapping.

Technique

Catheter ablation is usually performed immediately subsequent to diagnostic electrophysiology. It is important to discontinue antiarrhythmic medication, if at all possible, prior to the procedure as the effects may render arrhythmias non-inducible and make it impossible to find the site for ablation. In some laboratories, systemic heparinisation is used during the procedure regardless of ablation location; others only heparinise for left-sided ablations or if arterial access is required.

Once the arrhythmic substrate has been determined and mapped, an ablation catheter is advanced via an additional

site of access, usually the femoral vein or artery, to the appropriate site for delivery of energy. Energy can be delivered during sinus rhythm, during tachycardia, or during atrial or ventricular pacing. In radio-frequency ablation, a short test application of 10 seconds or so, which usually does not cause irreversible changes, will be continued for 30 to 90 seconds if the test causes the desired effect, such as loss of the delta wave, termination of tachycardia, or loss of retrograde conduction.⁷⁶ Ineffective ablation may occur as a result of inexact localisation of the site, poor contact between the ablation catheter and the endocardium, or build-up of coagulum and char on the electrode tip. These problems will need to be corrected before ablation is successful. Moving the catheter to a new site guided by the electrograms is often sufficient but, if there is repeated failure, then different catheter shapes and approaches to enhance contact between catheter and endocardium should be utilized. Long sheaths with a variety of shaped tips are available to aid stability and positioning. Monitoring the impedance and temperature of a radio-frequency catheter allows delivery of the minimal energy to raise the temperature at the tip to 60° to 70°C without creating charring, which then impedes effective delivery of energy to the tissue. If necessary, the catheter is removed from the body and the char and coagulum wiped off with a saline swab. Further attempts are made until success is achieved.

Following a successful ablation, attempts are made to re-induce the tachycardia. If the ablation appears to be successful, repeat attempts to induce are made 20 to 30 minutes later, as occasionally there is recovery of the ablated area.

Placement of Electrophysiologic Catheters

Bipolar or quadripolar catheters for pacing and sensing are usually placed in the high right atrium, in the right ventricular apex, and through the antero-superior part of the tricuspid valve to record the electrical activity of the His bundle (Fig. 19-2). A multi-polar catheter is placed in the coronary sinus to record left atrial and left ventricular electrograms around the left atrioventricular groove. At least four different sheaths for venous access are required to place these electrodes. These are usually inserted through three or four sites of femoral venous puncture and/or a puncture in the subclavian or jugular vein for access to the coronary sinus. In some cases, additional electrode catheters are inserted to increase the number of sites for recording and pacing, or to serve as anatomical landmarks. Electrodes are not routinely placed in the left ventricle or left atrium unless this is indicated during the course of the study.

Programmed Stimulation and Intracardiac Recordings

The recordings of the intracardiac electrograms are used to measure the intracardiac conduction times in the baseline state. Following this, a variety of pacing protocols are used to characterise the electrophysiological properties of the atriums, ventricles, and cardiac conduction system and to induce tachyarrhythmias. The specific protocols used, and their order, will depend on the clinical indications for the study and the information emerging during the course of the study.^{77,78} After any intervention, be it administration of drugs or ablation, the electrophysiological properties of the heart are re-evaluated.

Conduction Intervals

The PA interval is a measurement of the intra-atrial conduction time, the AH interval is a measurement of the atrioventricular nodal conduction time, and the HV is

a measurement of the His–Purkinje conduction time (Fig. 19-3). Conduction intervals are generally measured in sinus rhythm and then during atrial pacing.

Sinus Node Function

Sinus node function can be assessed by pacing the atrium at a constant rate for 30 seconds and measuring the length of the pause after the pacing is stopped. This is the sinus node recovery time. Sinus node disease is uncommon in children unless they have had extensive atrial surgery, as in the Senning, Mustard, or Fontan operations. Clinical evaluation is usually sufficient.

Atrioventricular Conduction

Atrioventricular node conduction is assessed by measuring conduction intervals at baseline and during incremental atrial pacing until the development of atrioventricular Wenckebach, and by using atrial extrastimuli. Ventriculo-atrial, or retrograde, conduction is assessed during ventricular pacing and extrastimulation. Conduction via the atrioventricular node is distinguished from that of accessory pathways by the response to extrastimuli, as well as the location of the earliest activation. Atrioventricular nodal tissue demonstrates a decremental pattern in which conduction time increases the earlier the extrastimulus. Conduction across accessory pathways, in contrast, is non-decremental. Therefore, the conduction time remains constant with increasing prematurity of the extrastimulus until there is a sudden loss of conduction.

Incremental Pacing

Pacing is started at a low rate and gradually increased until conduction is blocked or a tachycardia is induced. This is used to assess atrioventricular conduction, to expose accessory pathways and to induce tachycardias.

Burst Pacing

Rapid atrial pacing is commenced at rates of 200 to 600 beats/min in order to induce atrial flutter and atrial fibrillation. Burst pacing is generally not performed in the ventricle, and certainly not at rapid rates, due to the risk of induction of a haemodynamically unstable rhythm.

Extrastimulus Testing

Timed extrastimuli, so-called premature beats, can be introduced during sinus rhythm or following a train of pacing, usually comprising eight beats, that stabilises the electrophysiological properties of the tissue before the extrastimulus. Successive extrastimuli are introduced with increasing prematurity. When the coupling interval between the last beat in the train and the extrastimulus is shortened sufficiently that the extrastimulus is unable to excite the tissue, then the refractory period of the tissue has been identified. This is called the effective refractory period. Atrial extrastimuli are used to measure the effective refractory period in the atrium, of the atrioventricular nodal conducting system and, when present, of accessory pathways that conduct from the atrium to the ventricle. They are also used to expose dual atrioventricular nodal pathways. Ventricular extrastimuli are used to measure the effective refractory period in the ventricle and expose concealed accessory pathways, in other words those pathways that conduct only from ventricle to atrium. Single, double, or triple extrastimuli, either in sinus rhythm or following a drive train, are introduced with increasing prematurity to induce atrial, ventricular, and atrioventricular re-entry tachycardias. Extrastimuli introduced during tachycardia can be used to help to characterise the tachycardia or to terminate it.

Figure 19-2 Catheter electrodes positioned in the high right atrium, right ventricular apex, site of the His bundle, and coronary sinus (poles labelled). The fluoroscopic views are frontal (A), left anterior (B), and right anterior (C) orientations.

Tachycardia Mapping

Mapping of the site of origin of the tachycardia, or of sites critical to maintenance of a re-entry circuit, is necessary for planning interventions to interrupt the tachycardia. One or more of the following methods are used for this purpose.

Activation Mapping

During ectopic tachycardias, an electrode catheter is moved to find an intracardiac electrogram with an onset that is earlier than that of any other intracardiac or surface electrogram. The earliest onset atrial or ventricular electrogram

Figure 19-3 Intracardiac and surface electrograms. CS, coronary sinus poles 1–10; HRA, high right atrium; H, His (proximal and distal); RV, right ventricle.

will be found close to the site of origin of an ectopic atrial or ventricular focus. For tachycardias using an accessory pathway, the earliest onset of a retrograde atrial electrogram or antegrade ventricular electrogram on the atrioventricular groove will be at the site of the accessory pathway. It may be possible to determine this during sinus rhythm, in atrial or ventricular pacing, or during re-entry tachycardia, depending on the characteristics of the pathway.

Electroanatomic Mapping

In recent years, electroanatomic mapping systems have become more widely used, in conjunction with traditional fluoroscopy and activation mapping. These systems utilise electromagnetic fields to identify the location of a catheter in three-dimensional space. Using these systems the anatomy of the area of interest can be mapped, and location of catheters tracked. Ideally these systems will offer better definition of anatomic substrate, and reduce fluoroscopy times. Once the anatomy is defined, colour-based timing maps can be created and superimposed on the anatomical map (Fig. 19-4).

Figure 19-4 Electroanatomical map of an ectopic atrial tachycardia. The white area indicates the earliest timing at the roof of the left atrium, while colours red to purple indicate later and later timing. The yellow ball shows the site of successful ablation.

Pace Mapping

During sinus rhythm, an electrode catheter is used to pace from different sites until the paced pattern on the surface 12-lead electrocardiogram and the intracardiac electrogram are identical to that seen during the tachycardia. This method is used when an atrial or ventricular tachycardia is not sustained for sufficiently long to use activation mapping, or if a ventricular tachycardia is not sufficiently well tolerated haemodynamically.

Entrainment Mapping

Entrainment mapping is used for re-entrant circuits in the atrium or ventricle where the tachycardia is maintained by an area of slow conduction. Pacing at a rate just faster than the tachycardia will entrain the tachycardia so that the paced beat is conducted around the circuit slightly earlier than the next beat of the tachycardia circuit would have done. Manifest entrainment occurs when the pacing site is remote from the area of slow conduction of the tachycardia circuit. The intracardiac and surface leads will reveal a fusion pattern composed of the paced beat and the preceding beat that is emerging from the area of slow conduction. Concealed entrainment is inferred when the intracardiac and surface leads demonstrate identical electrograms to that of the tachycardia. This implies that the pacing electrode is close to the site of slow conduction. This site is critical for maintenance of the tachycardia and provides a target for interruption of the circuit. Observation of the events immediately after pacing is terminated also help to locate the critical site of slow conduction.^{79–81}

Administration of Drugs during Catheterisation

When it is difficult to induce an arrhythmia in the basal state, sympathomimetics, such as isoprenaline (isoproterenol) given as a bolus or an infusion, are used to initiate or reduce the threshold for the arrhythmia. Further information on the mechanism of the arrhythmia may be obtained by administering drugs during pacing and/or tachycardia. Adenosine is a short-lived inhibitor of atrioventricular nodal conduction and is particularly useful. Verapamil is used to produce more sustained atrioventricular block. Atropine and propranolol are given together to produce autonomic blockade. Disopyramide is used to expose impairment of atrioventricular nodal conduction, ajmaline or procainamide to abolish conduction down an accessory pathway, and flecainide to terminate atrial fibrillation.^{82,83} These antiarrhythmic agents, however, have more sustained effects than adenosine. While providing additional information, they may interfere with the remainder of the study. Some of these medications are also used in the diagnosis of inherited arrhythmias, described previously in this chapter.

Indications for Ablation

The indications for ablation have evolved since its introduction, with expansion of the arrhythmic substrates to which it is applied. This has led to a significant fall in the use of anti-tachycardia pacemakers and antiarrhythmic surgery. The threshold for intervention has also fallen, and patients who were previously well or could be controlled on medication, now undergo radio-frequency ablation in preference to chronic antiarrhythmic medication.⁸⁴ It is still not considered by many as first-line therapy in children

weighing less than 15 kg, because the rate of complications is higher, and many of these children will lose the tendency to continued tachycardias with aging.⁸⁵

ARRHYTHMIAS

Atrioventricular Re-entry Tachycardia

Atrioventricular re-entry tachycardia due to an accessory atrioventricular pathway is the commonest cause of tachyarrhythmia in the fetus, and in early childhood.⁸⁶ A minority are associated with hydrops fetalis, fetal death, or heart failure in the neonatal period. Infants presenting with supraventricular tachycardias should be evaluated for possible tachycardia-induced cardiomyopathy, as the duration of the arrhythmia is generally unknown; it is essential to confirm cardiac function prior to initiation of medications with potential negative inotropic effects, such as many of the antiarrhythmic medications. In addition echocardiography should be performed in all patients who have supraventricular tachycardia to identify structural lesions associated with accessory pathways. Some of these may be clinically silent and include Ebstein's malformation, congenitally corrected transposition, myocardial tumours, and hypertrophic and dilated cardiomyopathy.

In older children, symptomatic tachycardias are the usual presentation. Approximately one-third will have evidence of pre-excitation, with a delta wave on the surface electrocardiogram, indicating an overt accessory pathway. In the remainder the pathway is concealed. In these patients only retrograde conduction occurs, from the ventricle to the atrium, thus no change in depolarisation of the ventricle is seen in sinus rhythm. In the majority of children, the tachycardia is easily controlled with drugs. Many neonates and infants will be free from arrhythmias by the age of 1 year, without the need for medication. However, 30% to 50% do not outgrow the tendency to recurrent tachyarrhythmias, and of those who do, a small proportion have a recurrence in later childhood.⁸⁷ When tachycardias persist over the age of 5 years, about four-fifths continue to experience intermittent symptomatic tachycardias into adulthood.⁸⁸

Arrhythmic Substrate

The accessory pathway permits retrograde conduction from the ventricle to the atrium; consequently a re-entry circuit can be established (Fig. 19-5). An early atrial extrasystole is conducted slowly down the atrioventricular node to the His-Purkinje system and ventricle; it returns to the atrium over the accessory pathway. If the atrioventricular node has recovered and is no longer refractory, then a circus movement tachycardia, also known as re-entry tachycardia or reciprocating tachycardia, can be established. A ventricular extrasystole can also trigger tachycardia in this situation, via retrograde conduction up the accessory pathway into the atrium, with the retrograde P wave then being conducted anterograde across the atrioventricular node. Following ventricular depolarisation, there is conduction back up the accessory pathway, and the tachycardia is initiated.

Histology of the accessory pathways shows that they are composed of abnormal myocardium that crosses the atrioventricular groove. They have been found around the left atrioventricular groove at the level of attachment of the mural leaflet of the mitral valve, and around the right atrioventricular groove at the level of attachment of all three tricuspid valvar leaflets. There is no atrioventricular

Figure 19-5 Substrates for arrhythmias that may be amenable to ablation: (1) unidirectional concealed accessory pathway; (2) slowly conducting accessory pathway, such as permanent junctional reciprocating tachycardia; (3) atrioventricular nodal re-entrant tachycardia; (4) focal atrial tachycardia; (5) intra-atrial re-entrant tachycardia; (6) fascicular tachycardia; and (7) ventricular tachycardias

junction around the aortic leaflet of the mitral valve where it joins the aortic valve. The right atrioventricular groove is thicker because of infolding of the atrial myocardium at the tricuspid valvar origin. In one-tenth of patients, there are multiple accessory pathways. Accessory pathways may be described as right-sided, left-sided, or septal, and as superior, inferior, or lateral (Fig. 19-6).⁸⁹

Electrophysiological Findings

Atrioventricular re-entry tachycardia can be induced with atrial and ventricular extrasystoles or by pacing manoeuvres. During atrioventricular re-entry tachycardia, the earliest retrograde atrial electrogram will be detected at the atrial origin of the accessory pathway rather than at the atrioventricular node. During ventricular pacing, there may be fusion between retrograde conduction via the accessory pathway and atrioventricular node. Adenosine can be used to block the conduction through the node, thus exposing conduction via the accessory pathway, although a small percentage of accessory pathways are also adenosine sensitive. When overt pre-excitation is present, incremental atrial pacing may increase the degree of pre-excitation due to normal decrement in the atrioventricular node conduction time. Pre-excitation can also be accentuated by atrial pacing close to the accessory pathway. The earliest site of ventricular activation will be at the ventricular insertion of the accessory pathway. The ventricular electrogram frequently will be seen 10 to 30 msec prior to the onset of the delta wave on the surface electrocardiogram. At the site of the accessory pathway, there may be fusion between the atrial and ventricular electrograms to form a continuous signal. In some instances, it may be possible to see a discrete potential generated by the accessory pathway.⁹⁰ Left-sided pathways can be localised by electrodes in the coronary sinus; detailed mapping is performed using catheters moved around the atrioventricular ring. Accessory pathways that are close to the His bundle (para-Hisian pathways) may

Figure 19-6 Diagram of the locations of accessory pathways comparing (A) the traditional surgical perspective and (B) an anatomically correct nomenclature, as proposed by Cosio and colleagues.

be more difficult to differentiate from conduction via the atrioventricular node. Some accessory pathways have properties of decremental conduction and may be adenosine-sensitive, making differentiation from the atrioventricular node challenging at times.

Ablation

Left-sided pathways are accessed either via an antegrade or retrograde approach. The antegrade approach uses a patent oval foramen or requires a trans-septal puncture to place lesions on the atrial side of the atrioventricular ring. The retrograde transarterial approach requires the catheter to cross the aortic valve and be looped up under the leaflets of the mitral valve for delivery of lesions on the ventricular side of the ring. Using this route, it is also possible to cross the mitral valve and apply the lesions on the atrial side. Ablation is guided anatomically and electrographically by placing a multi-polar electrode catheter in the coronary sinus. This allows the ablation catheter to be aimed at the poles in which the earliest activation is detected (Fig. 19-7). Right-sided and septal pathways are usually approached from the inferior caval vein, though occasionally approach via the superior caval vein is required. Lesions are usually placed on the atrial side of the atrioventricular ring or in

the mouth of the coronary sinus, but it may be necessary to loop the catheter in the right ventricle to ablate on the ventricular side of the atrioventricular ring. A diverticulum of the mouth of the coronary sinus is occasionally found, and an accessory pathway may run in the floor of the diverticulum, which can be identified with angiography. The ablation catheter is placed on the atrioventricular ring and moved around its circumference to identify the earliest activation. In difficult cases, where delivery of energy at the site of the earliest activation is ineffective, an intracoronary electrode catheter can be used. The catheter defines the right coronary artery, and thereby the right atrioventricular groove, and also provides electrograms so that a stable reference electrogram at the site of earliest activation can be identified to guide the ablation catheter (Fig. 19-8). The existence of additional accessory pathways that can sustain arrhythmias may only become apparent after successful ablation of the first pathway; these will also be ablated at the same procedure if possible. Mapping is always more challenging when multiple pathways are present, due to the potential for fused or figure-of-eight conduction (in which the impulse travels alternately between the two pathways, sometimes suggested by alternating tachycardia cycle length).

Ablation of left-sided pathways has a success rate of more than 90% in most centres, and the success rate increases with experience. Right-sided pathways are technically more challenging. Placement of catheters on the right atrioventricular junction is less stable and some pathways are epicardial. Nonetheless, success rates are generally above 80%. The use of long sheaths to stabilise the catheter may be helpful. Septal and paraseptal pathways can also be ablated with a high degree of success, but this does carry a risk of complete heart block owing to inadvertent damage to the atrioventricular node and bundle of His. Some centres advocate the usage of cryoablation in these situations, due to the potential reversibility of lesions. A high rate of success has also been reported in infants and neonates with intractable re-entry tachycardias, but with higher rates of complications, including major complications.⁹¹⁻⁹⁴ Ablation in the infant should be reserved for those with medically refractory life-threatening arrhythmias likely to respond to ablation.

Other Types of Accessory Pathways

Mahaim Fibres

Structures similar to the atrioventricular node are occasionally found in the anterolateral right atrium adjacent to the atrioventricular ring.⁹⁵⁻⁹⁷ They usually connect to the right bundle branch, or to the right ventricle in the vicinity of the moderator band. These so-called atriofascicular accessory pathways mediate Mahaim-type physiology, conducting predominantly in an antegrade fashion, with a left bundle branch pattern in tachycardia. Retrograde conduction is through the atrioventricular node or an additional conventional accessory pathway. They demonstrate decremental conduction similar to that of the atrioventricular node, and they give rise to a Mahaim potential that is similar to a His bundle potential during atrial pacing. They are thought to arise from remnants of the ring of conduction tissue that surrounds the atrioventricular junction during early fetal development. Ablation can be performed at the

Figure 19-7 Ablation of a left-sided accessory pathway. Fluoroscopy in left anterior (A) and right anterior (C) oblique projections. B, Electrograms recorded during ablation with abolition of conduction across the accessory pathway. CS, coronary sinus; HRA, high right atrium; RF, radio-frequency; RV, right ventricle.

atrioventricular ring, or anywhere along the pathway up until its point of insertion within the ventricle.⁹⁸⁻¹⁰¹

A much rarer accessory pathway is one that is acquired after surgical manoeuvres that connect the atrial myocardium to the ventricle, as in the earlier variants of the Fontan

operation. These pathways between the atrial appendage and right ventricular outflow tract can also be ablated successfully.^{56,102} Equally rarely, congenital muscular pathways can be found between the right atrial appendage and the supraventricular crest of the right ventricle.^{103,104}

Figure 19-8 A, 2 French quadripolar electrode in the right coronary artery (RCA) through a coronary guide catheter to assist ablation of a right-sided manifest accessory pathway after a previous attempt had failed. B, Electrograms from surface and intracardiac leads show that the shortest atrioventricular conduction time is at the distal pair of electrodes on the catheter within the right coronary artery. The ablation catheter shows continuous atrioventricular signals at the site of successful ablation. CS, coronary sinus; HRA, high right atrium; RV, right ventricle.

Wolff-Parkinson-White Syndrome

Electrocardiographical evidence of manifest accessory atrioventricular pathways is found in up to 3 of every 1000 of the population.^{105,106} The incidence is increased in family members, and in those with a congenitally malformed heart, especially Ebstein's malformation and congenitally corrected transposition.^{107,108} These allow pre-excitation of parts of the ventricle before the normal impulse can arrive via the His-Purkinje system. When more myocardium is pre-excited, a wider QRS complex and more overt delta wave is seen. The pattern of the delta wave and QRS complexes can be used to identify into which portion of the ventricle the accessory pathway inserts. A number of algorithms have been developed. These algorithms correlate reasonably, though not absolutely, with the findings at electrophysiologic study.^{109–112} When multiple pathways are present, or pre-excitation is only partial or intermittent, the electrocardiographic pattern can vary, making localisation from the surface recordings impossible. Right-sided pathways are more common in patients with congenital heart disease, and the algorithms are much less accurate in these patients.^{113,114}

Atrioventricular re-entry tachycardia is possible because of retrograde conduction across the pathway, but not all Wolff-Parkinson-White pathways are capable of sustaining such tachycardias, due to weak or nonexistent retrograde conduction. Many patients are therefore asymptomatic, and the diagnosis is often established as an incidental finding when an electrocardiogram is performed for another reason. Patients with a delta wave and symptoms of palpitations or documented tachycardia have Wolff-Parkinson-White syndrome, while those with an asymptomatic delta wave have only the electrocardiographic phenomena of Wolff-Parkinson-White.

By definition, the manifest pathways are capable of antegrade conduction from the atrium to the ventricle.

Occasionally, an antidromic circus movement tachycardia is set up with antegrade conduction down the accessory pathway and retrograde conduction via the atrioventricular node or a second accessory pathway. Pre-excitation of the ventricles in this rhythm results in a broad complex tachycardia, due to all ventricular activation occurring via the accessory pathway. Those patients who demonstrate this form of tachycardia usually also have typical orthodromic tachycardia.

Risk of Sudden Death

Wolff-Parkinson-White patients are at higher risk than the general population of developing atrial fibrillation, which may be conducted rapidly to the ventricle bypassing the atrioventricular node. This results in a broad complex irregular tachycardia. If the atrial fibrillation is conducted at a very rapid rate, then the ventricles may not be able to maintain cardiac output and even more rapid conduction can cause the ventricle to fibrillate. These patients can present with syncope or out of hospital arrest and sudden death.¹¹⁵ Pre-excited atrial fibrillation or Wolff-Parkinson-White with syncope is an indication for ablation, as these patients are known to be at higher risk of ventricular fibrillation and sudden death.

Controversies in Management

There are no absolute predictors of a benign or malignant prognosis in asymptomatic patients with Wolff-Parkinson-White syndrome. Intermittent episodes, with sudden loss of the delta wave on exercise or after administration of class I antiarrhythmic drugs, suggests a benign prognosis, as pathways with this feature tend not to be able to conduct very rapidly.^{82,116} The onset of symptoms, palpitations, or tachycardia suggests that the risk of sudden death is increased. When syncope is a symptom, then there is a very real risk of sudden death. Sudden death or out-of-hospital cardiac arrest can, however, be the first symptom in the previously asymptomatic patient. For this reason,

Figure 19-9 Pre-excited atrial fibrillation with extremely rapid conduction to the ventricle, consistent with a high risk Wolff–Parkinson–White accessory pathway.

attempts have been made to identify those asymptomatic patients at increased risk.

During an electrophysiological study, rapid atrial pacing is used to induce atrial fibrillation. If atrial fibrillation can be induced, the shortest interval between two pre-excited beats is measured. Intervals less than 220 msec, indicating a rate of 270 beats per minute, are defined as very rapid conduction over the pathway, thus identifying high-risk pathways. If atrial fibrillation is not able to be induced, then the antegrade effective refractory period is measured during rapid atrial pacing, though this may be less predictive than that measured during atrial fibrillation¹¹⁵ (Fig. 19-9). Most patients who present with syncope or cardiac arrest demonstrate very rapid conduction over the accessory pathway. Asymptomatic patients, or those with tachycardia without syncope or cardiac arrest, may also demonstrate such rapid conduction. So, while slow conduction may identify a group at low risk, rapid conduction does not necessarily identify the patients at high risk.¹¹⁶ Nevertheless, routine electrophysiological testing to distinguish between rapid and slow conductors is performed in many laboratories. Those found to have rapid conduction can be offered an ablation, accepting that not all are at high risk. It is also important to note that accessory pathway conduction rates under sedation or anaesthesia may not completely reflect those seen while awake or during exercise. When the pathway is located away from the septum, this can be performed at low risk of the complication of heart block and with a high rate of success. Ablation of pathways that are close to the septum carry a small but definite risk of complete atrioventricular block and the need for a permanent pacemaker. Pathways in the inferior paraseptal area, however, are also thought to potentially carry a greater risk of sudden death.¹¹⁷

The risk of sudden death is around 1 per 1000 patient-years of follow-up with the syndrome, while the mortality of ablation is similar (Table 19-1).^{118,119} Therefore, the argument is finely balanced, and some centres do not offer electrophysiological study and ablation to asymptomatic patients. Electrophysiological study and ablation are easier to recommend in individuals undertaking extreme exertion or in those requiring a license to fly, or other occupations in which those with pre-excitation are excluded. In asymptomatic children, an electrophysiological study is often recommended in adolescence, but sudden death has also

been reported in young children.^{120,121} In some centres, early electrophysiological studies are performed, using a transoesophageal electrode. There is still no universally accepted policy, and the controversy remains.^{122,123}

Atrioventricular Nodal Re-entry Tachycardia

Atrioventricular nodal re-entry tachycardia is an uncommon arrhythmia in the first year of life; it becomes more frequent with increasing age thereafter.

Arrhythmic Substrate

The anatomic substrate is the presence of dual atrioventricular nodal pathways, which allow a re-entry circuit to form in the atrioventricular node, for example, after an atrial

§Excludes 900 patients who underwent ablation of the atrioventricular node to produce complete heart block. Includes a significant proportion of ablations of the fast pathway for nodal re-entry tachycardia.

extrasystole. Typical nodal re-entry occurs when antegrade conduction across the atrioventricular node is blocked in a more rapid conduction region, called the fast pathway, and then conducts slowly down a region of slower conduction, called the slow pathway. By the time the impulse has crossed the atrioventricular node, the fast pathway has recovered and is no longer refractory. The impulse is then able to conduct back up the atrioventricular node retrograde to the atrium. The slow pathway has then recovered and conducts antegrade down the atrioventricular node (Fig. 19-10), and thus the tachycardia is propagated. These pathways are well defined electrophysiologically, but not so clearly histologically. The slow pathway is associated with the junction of working atrial myocardium, atrial transitional cells, and the inferior extension from the compact atrioventricular node in the area of the septal isthmus at the base of Koch's triangle.^{124,125} The fast pathway is usually located more anteriorly near the apex of the triangle of Koch and is associated with transitional atrial cells in that area. The arrhythmia is usually well-tolerated haemodynamically, but can be recurrent and symptomatically poorly tolerated. Atrioventricular nodal blocking drugs, such as digoxin, beta blockers, and verapamil, will usually suppress the arrhythmia, but the ability to cure it by ablation is appealing.^{126,127}

Electrophysiological Findings

At electrophysiological study, the typical finding during timed atrial extrastimulation is the presence of a jump in the atrioventricular conduction times when the fast pathway blocks and conduction occurs down the slow pathway. This is seen as a sudden extension in the atrial to His bundle electrogram interval of more than 50 msec in adults. This may then be followed by an echo beat, owing to retrograde conduction up the fast pathway to the atrium, which often sets off the tachycardia. The presence of dual atrioventricular nodal physiology is more common than re-entry and tachycardia, and at electrophysiological studies it must be confirmed that

the tachycardia is caused by re-entry within the node before undertaking an ablation. Dual atrioventricular nodal physiology may be present when there is another arrhythmic substrate that is responsible for the clinical tachycardia. This is particularly true in children, where dual atrioventricular nodal physiology is seen in as many as one-third of all children. Nodal re-entry may only be induced with rapid pacing or after administration of isoprenaline. The tachycardia can also occasionally be induced with ventricular extrastimulation or pacing, but much less frequently.

Ablation

Lesions are delivered into the septal isthmus at the base of the triangle of Koch to ablate the slow pathway. Some are guided by electrograms that reveal so-called slow pathway potentials, while others are guided by the anatomical landmarks alone.^{128,129} During delivery of radio-frequency energy in the septal isthmus, accelerated junctional beats are a good indicator that energy is being delivered at the correct site, although this may not be essential for eventual success.¹³⁰ It is important to observe closely for any evidence of damage to atrioventricular conduction, as there is a small risk of inadvertent complete atrioventricular block. When a successful ablation has been achieved, it is no longer possible to initiate tachycardia, even though a jump and even an echo beat may remain. The procedure has an acute success rate approaching 100%, with greater than 90% long-term freedom from recurrence. In adults, persistence of the slow pathway appears to be a risk factor for recurrence.¹³¹ There is a small risk of creating complete atrioventricular block.^{84,132,133} This risk is likely significantly less if cryoablation is used; however, the recurrence rate may be higher. Some centres have chosen to use cryoablation exclusively for this diagnosis in children, while others still find the higher recurrence rate unacceptable. In small children weighing less than 15 kg, the triangle of Koch has dimensions similar to that of a single radio-frequency lesion and the margin for error is, therefore, smaller.¹³⁴ Ablation of the fast pathway carries a higher risk of inadvertent complete atrioventricular block, this complication occurring in up to one-tenth of patients even in experienced centres. Because of this, it is now rarely performed.¹³⁵

Ectopic Atrial Tachycardia

Ectopic atrial tachycardias can arise from foci in either atrium. It may present at any age from fetal life onwards. It is a relatively uncommon arrhythmia but when incessant can cause a rate-related tachycardiomyopathy.

Arrhythmic Substrate

The arrhythmia is caused by an automatic focus in the atrium, which may be intermittent or incessant. During tachycardia, the surface P wave indicates the site of origin, with inverted P waves in inferior leads indicating a low right atrial tachycardia, while inverted P waves in lead I suggest a left atrial origin. Tachycardias that originate close to the sinus node, such as on the crista terminalis, can be extremely difficult to differentiate from sinus tachycardia. The tachycardia may be transmitted to the ventricles in a 1:1 fashion, but atrioventricular block of varying degrees is often present, or can be produced by vagal stimulation or adenosine without terminating the tachycardia. Some atrial tachycardias, however, are terminated by adenosine or may slow and then accelerate as the adenosine is metabolised.

Figure 19-10 Induction of atrioventricular nodal re-entry tachycardia using a drive train (S1) and a single atrial extrastimulus (S2). The solid bar indicates conduction down the fast pathway and the hollow bar indicates conduction down the slow pathway. During the drive train, conduction from the atrium to His bundle is via the fast pathway. After the extrastimulus (S2), the fast pathway is blocked and conduction proceeds down the slow pathway to the His bundle (AH jump). At this point the fast pathway has recovered and conducts retrograde so that the A and V are superimposed in the His bundle electrode and a retrograde A is detected in the high right atrium and coronary sinus leads. Antegrade conduction is via the slow pathway and a re-entry tachycardia follows. CS, coronary sinus; HRA, high right atrium; RV, right ventricle.

Electrophysiological Findings

Timed atrial extrastimulation is not able to start or stop most ectopic atrial tachycardias reproducibly, as they are automatic in nature, in contrast to atrioventricular re-entrant tachycardias. Occasionally these arrhythmias can be triggered, and rapid atrial pacing may initiate such tachycardias. More frequently the rhythm is catecholamine sensitive, and an infusion of isoprenaline may be helpful for initiation. The tachycardia characteristically speeds up as it starts, and slows before termination, usually described as a warm-up and cool-down. It is frequently difficult to initiate the tachycardia under general anaesthesia, and consideration should be given to performing the procedure using sedation and local anaesthesia. Post-operative ectopic atrial tachycardia can be associated with a variety of congenital heart disease repairs, and appears to be most frequently seen in sicker cyanotic children, although the aetiology is multi-factorial. In the post-operative setting, this rhythm can be haemodynamically compromising, requiring multiple medications, but usually will resolve spontaneously.¹³⁶

Ablation

Left-sided foci, often near the pulmonary veins, are approached via the atrial septum either using a patent oval foramen or a trans-septal puncture, while right-sided foci are generally approached from the inferior caval vein. The ablation catheter is placed at the site of the earliest activation in the atrium that occurs before any other intracardiac atrial electrograms and the surface P waves. At the site of the focus, there may be very early local activation and/or fractionation of the atrial signal. Pacing from the site of origin will produce surface P waves identical to that from the tachycardia, and identical patterns of atrial activation in the intracardiac electrodes. Radio-frequency ablation can be performed with 75% to 90% success.^{137,138} The use of multi-electrode techniques may facilitate mapping in difficult cases.¹³⁹

Chaotic Atrial Tachycardia

Chaotic atrial tachycardia is an atrial tachycardia related to abnormal impulse formation where not one, but many atrial foci fire prematurely (at least three atrial foci

are required to make the diagnosis). It can be an incessant tachycardia, and thus monitoring for tachycardia-mediated cardiomyopathy is necessary. It has a different natural history than the similar multi-focal atrial tachycardia, which is an adult arrhythmia commonly in association with pulmonary disease. In children it can be seen in those with structurally normal hearts as well as those with congenital cardiac anomalies and hypertrophic cardiomyopathy. It can be a severe arrhythmia, which may be difficult to control even with multiple antiarrhythmic medications. However, following the acute phase of the disease (variable but often 1 to 2 years) spontaneous resolution can be seen in more than half the patients.¹⁴⁰ Ablation is not a good option, due to the multiple foci, and rate control, rather than achieving sinus rhythm, should be the goal of therapy.⁷⁸

Permanent Junctional Reciprocating Tachycardia

An important pattern to note on the surface electrocardiogram in some supraventricular tachycardias is a long RP interval. In permanent junctional reciprocating tachycardia, the P wave is of an abnormal morphology (a retrograde P wave) and closer to the succeeding R wave than the preceding R wave. This is different from nodal re-entry tachycardia, where the P wave is buried or very close to the QRS complex, or atrioventricular re-entry tachycardia, where the P wave is closer to the preceding R wave than to the successive R wave (Fig. 19-11). The long RP pattern results from a slowly conducting concealed accessory pathway, giving the persistent form of junctional reciprocating tachycardia. The differential diagnosis of these long RP tachycardias also includes atypical nodal re-entry where antegrade conduction is down the fast pathway and retrograde conduction is via the slow pathway, or an ectopic atrial tachycardia. However, the most common mechanism in children is the persistent or permanent reciprocating tachycardia caused by a slowly conducting concealed accessory pathway with decremental properties. Such pathways are most commonly found in an inferior paraseptal position and give rise to inverted P waves in the inferior leads of the surface electrocardiogram.^{141,142} Occasionally there may be multiple pathways.

Figure 19-11 A run of permanent junctional reciprocating tachycardia with typical long RP interval and retrograde atrial activation, which breaks to sinus on the second-last beat of the tracing.

Permanent junctional reciprocating tachycardia is often incessant. When the rate is not very fast, it can be mistaken for a sinus tachycardia unless note is taken of the abnormal morphology of the P waves. The rate-related tachycardiomyopathy may then be incorrectly ascribed to myocarditis or a post-viral dilated cardiomyopathy. While antiarrhythmic medication can suppress this tachycardia, it is often difficult to control, requires multiple medications, and usually recurs after withdrawing medication. Radio-frequency ablation is especially rewarding as it effects a cure and allows cardiac function to return to normal in those patients with tachycardia-mediated cardiomyopathy.^{94,143}

Atrial Flutter

Atrial flutter is an uncommon tachycardia in childhood, though it can be seen in fetal life and the newborn period. In the neonate, after return to sinus rhythm, it rarely recurs. Conversion to sinus rhythm can be accomplished via oesophageal overdrive atrial pacing, which is highly successful in the infant.⁴² In rare cases it will terminate spontaneously, and even less often will require direct cardioversion. Atrial flutter can also be seen as part of the spectrum of chaotic atrial tachycardia. In older children with structurally normal hearts, atrial flutter is an unusual arrhythmia, and may be associated with sick sinus syndrome. In congenital heart disease causing right atrial dilation, it may occur either before or after surgery and can cause additional symptoms and morbidity in its own right. Atrial flutter often responds poorly to prophylactic medication.

Arrhythmic Substrate

Early experimental studies have shown that in atrial flutter there is a macro re-entrant wavefront circulating around the atria.¹⁴⁴ Type I flutter, with negative P waves in the inferior leads, results from a circulating wavefront that passes around the tricuspid valvar orifice and up the terminal crest in a counter-clockwise direction. The hinge of the tricuspid valve forms the anterior boundary, while the posterior border of the circuit is formed by the junction of the inferior and superior caval veins with the terminal crest.¹⁴⁵ Elegant entrainment studies have shown that there is often an area of slow conduction between the inferior caval vein and the tricuspid orifice, which slows conduction and prevents the wavefront from reaching a refractory portion of the circuit before it has recovered.¹⁴⁶ This is also anatomically the narrowest portion of the circuit and is known as cavotricuspid, or inferior, isthmus. The causes of the delay are not clear.

Ablation

Ablation can be used in this condition by creating a line of block between any of the boundaries that constrain the circulating wavefront.^{147–150} Typically, a line of block created at the inferior isthmus is enough to prevent the arrhythmia. At this site, the distance between the boundaries is short and can be defined using radiographic and electrophysiological markers. In some centres, it is routine to use a halo catheter with 20 separate electrodes, which are placed in a ring around the tricuspid valve in the right atrium. This enables the activation sequence of the atrial flutter to be determined and also assists in deciding when an adequate line of block has been created. By pacing from the lower right atrium and the coronary sinus in turn, and

observing the activation sequence according to the halo and coronary sinus electrodes, it is possible to detect when bidirectional block has been created, as no conduction is then possible in either direction across the isthmus. The procedure can be simplified by using a smaller 10-pole catheter extending along the anterolateral right atrium to the isthmus, which still allows determination of bidirectional block.¹⁵¹ If this approach is not successful, lines of block can be created between the coronary sinus and the inferior caval vein, and between the coronary sinus and the tricuspid valve. More recently, it has been shown that the necessary lines can be created with greater accuracy using an electroanatomical mapping system.^{152–155}

Variants of Atrial Flutter

Atypical flutter, or type II flutter, is found when the wavefront moves in a clockwise direction. This variant may occur at a slightly faster rate, can co-exist with type I flutter in the same patient, and can also be ablated in the same fashion.¹⁵⁶ The results are less good when the heart is structurally abnormal and the boundaries of conduction are less clear, for example, in tricuspid atresia.

Intra-atrial Re-entry Tachycardias

Intra-atrial re-entry tachycardias are also called incisional re-entry tachycardias. They may occur when surgical scars have created areas of slow conduction and block around which the wavefronts may pass. Examples are atriotomy scars, atrial septal patches, intra-atrial patches, and baffles. There are frequently multiple circuits in patients with congenital heart disease, and therefore, successful ablation of one may not always result in clinical cure. This is particularly common after the Fontan operation with a dilated and scarred right atrium that may be under higher pressure. In this setting, more extensive electrophysiological mapping is required using multiple catheters and entrainment techniques to delineate the circuit and areas of slow conduction that might be targets for ablation. This is facilitated by using the electroanatomic mapping systems. Lines of block between two scars, or from a scar to a patch or a caval vein, are often required.^{156–159} A further constraint is the fact that new circuits may emerge after a successful ablation. While in some series there have been encouraging results acutely, more extended follow-up has shown recurrence rates of up to 50% at 2 years.^{153,154,159} Particularly in these patients, who may need multiple procedures, the newer non-contact balloon-mounted electrode arrays and non-fluoroscopic techniques are finding a role in improving the ability to map out the tachycardia circuit without excessive exposure to radiation. Use of irrigated catheters also appears to improve success rates.¹⁵³

Junctional Ectopic Tachycardia

The congenital form of junctional ectopic tachycardia (previously known as His bundle tachycardia) is the least common sustained arrhythmia in childhood. If uncontrolled, it can lead to left ventricular dysfunction and a tachycardiomyopathy with heart failure. Congenital junctional ectopic tachycardia may occur in siblings of affected patients. It has been proposed that maternal anti-SSA and anti-SSB antibodies may play a role in development of congenital junctional

ectopic tachycardia, suggesting a wider spectrum of AV nodal effects of maternal autoimmune disease.¹⁶⁰ This would also make sense, given the recognition that some patients go on to develop heart block, with or without antiarrhythmic medications. Children with the arrhythmia often require many years of medication to control the rate, although they may outgrow the tendency to arrhythmia in the second decade of life.¹⁶¹ The site of the ectopic focus, at the atrioventricular node, carries a risk of complete heart block after ablation, but a number of successful reports have appeared. Indeed, this was one of the earliest arrhythmias for which radio-frequency ablation was applied in children.¹⁶²

The more common form of junctional ectopic tachycardia is seen after cardiac surgery as a transient arrhythmia in the setting of a sick child. Although it can be seen after many congenital heart repairs, typical surgeries involve stretch or suturing close to the atrioventricular node, such as tetralogy of Fallot or perimembranous ventricular septal defect repair. It requires full supportive treatment in addition to treatment of the arrhythmia. Historically this arrhythmia was one of the causes of post-operative mortality due to haemodynamic deterioration, but with improved management this is no longer the case. Body cooling, medications (typically amiodarone or procainamide), and atrial pacing are usually able to control the arrhythmia, which does not recur once the acute post-operative phase has passed.¹⁶³

Ventricular Tachycardia

In the setting of a structurally normal heart, ventricular tachycardia is an uncommon arrhythmia in childhood. Some cases may be a result of myocarditis or a Purkinje cell tumour, usually presenting in the first few years of life. In these types of cases, after medical control has been achieved, it is often possible to withdraw treatment some years later without a recurrence of the arrhythmia, suggesting regression of the arrhythmic substrate.¹⁶⁴

Benign Ventricular Tachycardia

Arrhythmic Substrate

In the structurally normal heart, there are two common sites for an automatic focus, though they may occur at any site. Tachycardias originating in the right ventricular outflow tract are the most common and demonstrate a pattern of left bundle branch block on the surface electrocardiogram with an inferior axis. They may be sensitive to adenosine. More recently, subtle changes have been identified on resonance imaging scanning in some of these patients.¹⁶⁵ Left posterior fascicular tachycardias have a pattern of right bundle branch block with a superior axis. They are usually intermittent but can sometimes be incessant. Left anterior fascicular tachycardias have a pattern of right bundle branch block with an inferior axis. They are much less common. These tachycardias are often mistaken for supraventricular tachycardias and are responsive to verapamil.

Electrophysiological Findings

Timed ventricular extrastimulation may not be able to start or stop the right ventricular outflow tract tachycardia reproducibly. An infusion of isoprenaline is usually required for initiation if it is not spontaneously present. Ventricular pacing close to the site of the tachycardia origin is sometimes helpful in initiating tachycardia. Like most automatic foci, this can be challenging to induce under general anaesthesia.

Rapid atrial or ventricular pacing may be used to initiate a left fascicular tachycardia, and isoproterenol is also often helpful.

Radio-frequency Ablation

Radio-frequency ablation requires the catheter to be directed to the site of onset of the focus. Ventricular pacing at the site of origin will produce electrocardiographical recordings identical to that of the spontaneous arrhythmia. During ventricular tachycardia, an electrode catheter at the site of origin will detect ventricular activation that precedes the QRS complex in all of the surface electrocardiographical leads and any intracardiac reference electrodes (Fig. 19-12). A Purkinje potential may precede the ventricular activation at the site of a fascicular tachycardia.¹⁶⁶⁻¹⁶⁸ Radio-frequency ablation can be performed with reasonable success.¹⁶⁹⁻¹⁷¹

Post-operative Ventricular Tachycardia

Following repair of some forms of congenital heart disease, there is a small incidence of sudden death, which may occur many years after surgery. This is best recognised and studied in tetralogy of Fallot. In some patients, sustained ventricular tachycardias develop. This may be a precursor to the late complication of sudden death.^{172,173} A generalised increase in fibrous tissue is present when repair is late and may explain these late arrhythmias.^{174,175} In others, the origin of the tachycardia is in the subpulmonary outflow tract at the site of an infundibulotomy or transannular patch.^{13,176-178} The tachycardia may be caused by a localised area of re-entry or a much larger circuit around the infundibular scar. It can be initiated and terminated by programmed stimulation.^{179,180} Mapping of these tachycardias may be difficult and require a line of block to abolish the substrate. Mapping may also be difficult because rapid ventricular tachycardia is poorly tolerated haemodynamically. In order to map the tachycardia, it may be necessary to use pace mapping until close to the site of origin, then to perform closer mapping looking for early activation and mid-diastolic potentials indicating an area of slow conduction during short periods of induced tachycardia. Alternatively, a small dose of a class I antiarrhythmic agent can be given to slow the rate of the tachycardia to improve the haemodynamics during mapping. This strategy carries the risk of making the arrhythmia subsequently non-inducible. Mapping of single or a few

Figure 19-12 Activation mapping of a left fascicular ventricular tachycardia. The earliest activation on the ablation electrode is 64 msec ahead of the onset of the QRS complex in any of the surface ECG leads at the site of successful ablation. HRA, high right atrium; RV, right ventricle.

beats with non-contact electrode balloon arrays may minimise these problems.¹⁸¹ Less commonly, other structural defects may give rise to ventricular tachycardia after surgery as a result of scarring in the right ventricular outflow tract, for example, after repair of ventricular septal defect or pulmonary stenosis.^{182,183} Successful radio-frequency ablation is possible, but there are only anecdotal reports.¹⁸⁰ Frequently implantable defibrillators are the best choice in patients with established haemodynamically important ventricular tachycardia, if ablation is not a feasible or promising alternative.

INHERITED ARRHYTHMIA SYNDROMES

Primary electrical myopathies are frequently genetically based disorders, and thus frequently inherited. These diseases include the long QT syndromes, short QT syndrome, Brugada syndrome, arrhythmogenic right ventricular dysplasia/cardiomyopathy, familial hypertrophic cardiomyopathy (discussed elsewhere in this text), and catecholaminergic polymorphic ventricular tachycardia. Many of these diseases carry a significant risk of sudden death, as well as concomitant myocardial disease. A detailed discussion is beyond the scope of this chapter, but we briefly review the clinical syndromes.¹⁸⁴

Long QT Syndromes

Resulting from abnormalities in ion channel function, there are now multiple genes associated with the long QT syndromes. Ion channel abnormalities lead to abnormal repolarisation of cardiac muscle, creating vulnerability for malignant ventricular arrhythmias and sudden death. Standard therapy includes β -blockade for most types of long QT, and if patients remain symptomatic, pacing, left cardiac sympathetic denervation, and implantable defibrillator placement may be considered.^{185–187} Specific indications for device management are discussed in the pacing section of this chapter.

Brugada Syndrome

Brugada syndrome is characterised by ST segment elevation in the right precordial leads, right bundle branch block, and risk of sudden death due to malignant ventricular arrhythmias. Some patients have the Brugada QRS phenotype present on their electrocardiogram at baseline, while in others it is only evident with fever or through drug provocation with ajmaline, procainamide, or flecainide.¹⁸⁸ Therapy is most commonly placement of an implantable cardioverter defibrillator, although timing and risk stratification remain challenging.¹⁸⁹

Arrhythmogenic Right Ventricular Dysplasia/ Cardiomyopathy

Arrhythmogenic right ventricular dysplasia, like long QT syndrome, has been shown to be caused by several different mutations, leading to desmosomal dysfunction. Clinically it is characterised by fibro-fatty replacement of the right (and in advanced disease, the left) ventricular myocardium, causing myocardial dysfunction and ventricular arrhythmias. Implantable cardioverter defibrillators are

used frequently in this disease as well when life-threatening arrhythmias are seen.^{190,191} The use of ventricular stimulation studies for risk stratification remains controversial.¹⁹²

Catecholaminergic Polymorphic Ventricular Tachycardia

Catecholaminergic polymorphic ventricular tachycardia is a disease characterised by ventricular arrhythmias (typically bidirectional ventricular tachycardia which may degenerate into ventricular fibrillation) triggered by exercise or emotion. It is thought to be caused by mutations in the ryanodine receptor.¹⁹³ It is treated primarily with β -blockade, and then implantable defibrillator implantation in refractory cases.¹⁹⁴ Implantable defibrillator use in this population can be particularly difficult due to the possibility of electrical storm, where the pain and trauma of a shock reinduces the ventricular arrhythmia.

MISCELLANEOUS ARRHYTHMIAS

Radio-frequency ablation has also been applied to other arrhythmias, though less frequently in children.

Atrioventricular Nodal Ablation

In some patients with supraventricular arrhythmias, curative radio-frequency ablation is not possible. Good examples are some patients with atrial fibrillation, multi-focal atrial tachycardia, or multiple atrial re-entry tachycardias. In these settings, atrioventricular nodal ablation will prevent the atrial rate from being conducted to the ventricles. While this necessitates permanent pacing using either ventricular or dual chamber with mode switching, it allows a more stable ventricular rate. Although this was the original indication for ablation in adults, it has only a small role in paediatric practice. There is also an incidence of sudden death after successful catheter ablation of the atrioventricular junction despite implantation of a pacemaker. This may be because most of the patients in this group will have structural heart disease and/or ventricular dysfunction.⁵³ Ablation is performed from a venous approach placing the ablation catheter in a position to record a His bundle spike and then withdrawing it to increase the atrial signal. If this fails, then ablation can be performed via a transaortic approach on the left side of the septum.¹⁹⁵

Atrial Fibrillation

In adults with atrial fibrillation, two approaches have been taken. In some with focal fibrillation, ablation of a focus in one of the pulmonary veins has been effective.¹⁹⁶ In others, long lines of block, similar to those in atrial flutter, are created in the left and right atriums, or the pulmonary veins are isolated.¹⁹⁷ In recent years, success rates of atrial fibrillation ablation have increased, and its usage has increased.¹⁹⁸ Atrial fibrillation is uncommon in children and young patients with congenital heart disease. It becomes more frequent in older patients, particularly with untreated or palliated conditions. After the Fontan operation, multiple atrial arrhythmias may be present. It is conceivable that some of the strategies being developed for atrial fibrillation will be applicable in these patients.

Ectopic Beats

There are isolated reports of ablation for frequent, symptomatic ectopic beats in both the atriums and ventricles in patients with a structurally normal heart, using similar approaches to that for sustained arrhythmias at these sites.¹⁹⁹ The long-term utility of these strategies is unclear.

Inappropriate Sinus Tachycardia

In some patients who are highly symptomatic, the only arrhythmia documented is an inappropriate sinus tachycardia with an excessive rate response during mild exercise. When this is unresponsive to high doses of β -blockers and/or verapamil, ablation has been used in the past to reduce the resting heart rate and rate response to mild exercise, but this is no longer accepted at some centres.²⁰⁰ There is a risk of causing sinus bradycardia and the need for an atrial pacemaker, and this is a very unusual diagnosis in children. Consideration needs to be given to the important and more common differential diagnosis of postural orthostatic tachycardia syndrome, which has treatment other than ablation.²⁰¹ All efforts should be made to rule out a subtle ectopic atrial tachycardia, possibly including detailed mapping of the atrial focus.

Issues of Ablation in Congenital Heart Disease

Patients with structural congenital heart disease may present additional challenges for ablation strategies. Knowledge of the underlying anatomy, and of any previous surgery, is critical in planning and undertaking radio-frequency ablation. Despite some of the difficulties that may be encountered, it is important to consider radio-frequency ablation prior to surgery. Arrhythmias that are well tolerated pre-operatively may be less well tolerated after cardiopulmonary bypass. Inotropic support in the peri- and post-operative periods may accelerate and maintain haemodynamically unstable arrhythmias, and peri-operative atrial flutter may conduct rapidly (1:1) to the ventricle. In addition, access may be lost to relevant cardiac chambers; for example, venous access to the left atrium might be lost following completion of a Fontan. Anatomy, tissue scarring, and patient size are all sources for difficulties in ablation in congenital heart disease.^{108,114,154,202–204}

Vascular Access

Even in small children, it is possible to place multiple electrode catheters using both femoral veins as well as jugular and/or subclavian veins. In those who have undergone repeated cardiac catheterisation procedures, some of the points for central venous access may have become occluded. After the Glenn or hemi-Fontan operation, use of the neck and subclavian veins is no longer possible. This may mandate use of alternative sites, for example, a transhepatic approach, or necessitate using more catheters from one site, fewer catheters overall, or a transoesophageal catheter for atrial sensing and pacing. The development of smaller catheters, which will allow more catheters from one femoral vein, is an advance. It may be necessary to recanalise occluded veins using intravascular stents prior to ablation, with the assistance of intervention catheterisation colleagues.

Venous Anatomy

Azygos continuation of an interrupted inferior caval vein is usually associated with isomerism of the left atrial appendages. This may make manipulation of catheters more difficult, if not impossible, on the venous side of the heart when approaching through the femoral vein. Use of the superior caval vein, or hepatic veins, may facilitate manipulation.¹⁰⁸ A left-sided superior caval vein draining to the coronary sinus is an infrequent finding in patients with a structurally normal heart, but is more common in those with congenital heart disease. The resultant coronary sinus is dilated. While this is easier to catheterise, it may not provide electrograms from as close to the left atrioventricular valve ring as normal. In addition, passage of the catheter into the terminal portion of the coronary sinus to map accessory pathways in the left lateral and supero-lateral positions is more difficult. In patients with isomerism, the coronary sinus is often absent. Indeed, this is the rule in right isomerism. This removes a useful anatomical and electrical reference. Coronary angiography may help to localise the plane of the atrioventricular ring and confirm absence of the coronary sinus. Placement of a steerable 0.018-inch electrode into the left circumflex coronary artery can delineate the left atrioventricular groove anatomically and provide electrograms to help with mapping.

Cardiac Anatomy

Certain malformations impose constraints on the procedure. In Ebstein's malformation, the septal and mural leaflets of the tricuspid valve do not arise at the atrioventricular junction. The concomitant lack of valvar tissue makes stability of the catheter at the atrioventricular ring less secure. Frequently in this setting, there are multiple accessory pathways around the right atrioventricular ring. It is usually necessary to ablate all of them to abolish the tendency to arrhythmias. Similar problems occur when Ebstein's malformation occurs in the setting of discordant atrioventricular connections. The retrograde arterial approach may be more difficult, as placing the ablation catheter below the leaflets of the left atrioventricular valve will not be close enough to the atrioventricular ring. A trans-septal approach will enhance placement of the ablation catheter on the left atrioventricular ring.^{108,205} In patients with isomeric hearts, the plane of the atrioventricular ring may not fall into the usual fluoroscopy views. Transoesophageal echocardiography and angiography may help to locate the tip of the catheter and to define the plane of the atrioventricular ring.²⁰⁶ Where an atrial septal defect is present, access to the left atrioventricular ring is possible from a femoral venous approach. If surgery is planned, it is appropriate to perform the ablation prior to surgery to retain the additional route to the left atrioventricular ring. Similarly, if a Fontan operation is planned, then prior ablation can be performed via the femoral venous route. After surgery, the systemic atrioventricular valve can only be approached via the retrograde arterial approach and fewer mapping catheters can be placed.

Conduction System

In order to avoid inadvertent atrioventricular block during the procedure, it is vital to know the position of the bundle of His. The His bundle catheter helps both during analysis

of the arrhythmic substrate and as an anatomical marker. In patients with atrioventricular septal defects, the bundle of His is located more inferiorly than usual, towards the coronary sinus, and is more at risk when ablating inferior paraseptal accessory pathways. In patients with discordant atrioventricular connections, the bundle of His is located more anterosuperiorly, and is at risk during ablation in the superior paraseptal area. In left isomerism, there may be no discrete bundle of His, while in right isomerism there may be two atrioventricular nodes that form the substrate for twin atrioventricular re-entry tachycardias.²⁰⁷

Complications

The risks of the ablation procedure include all those seen with routine cardiac catheterisation and diagnostic electrophysiology but there are also a number of specific risks.^{121,204,208,209}

Complete Heart Block

The atrioventricular node is vulnerable during ablation of dual atrioventricular nodal pathways or accessory pathways in the parahisian areas. In the Paediatric Radiofrequency Catheter Ablation Registry, which carries records of almost 2000 ablations, the incidence of atrioventricular block was 1.6% for procedures for modification of atrioventricular nodal re-entrant tachycardia, 2.7% for superior paraseptal, 10.4% for septal, and 1.0% for inferior paraseptal accessory pathways.²¹⁰ These results improved slightly in the Pediatric Prospective Ablation Registry (radio-frequency ablations only), where AV block was uncommon overall at 1.2%; occurring in 2.1% of atrioventricular nodal tachycardia ablations, and 3.0% in septal accessory pathways ablations.²⁰⁸ There is a lower incidence when ablating ectopic atrial or ventricular focuses or accessory pathways in other areas unless the catheter moves during delivery of energy. When ablating in the para-Hisian areas, it is important to observe closely for any signs of atrioventricular block, either antegrade or retrograde, and to stop delivery of energy immediately when this occurs.²¹¹ In patients with life-threatening arrhythmias or disabling symptoms, the risk of creating complete heart block may occasionally be justifiable. This is likely not acceptable in small children with atrioventricular re-entry tachycardia, or in patients with Wolff-Parkinson-White syndrome, who are asymptomatic or at low risk. While complete heart block is usually apparent immediately, it may occasionally only become evident during the few weeks after the ablation.^{71,212} It is prudent to observe before proceeding directly to implantation of a permanent pacemaker in asymptomatic patients, as recovery is not uncommon in the first few days and can occur even as late as a month after the procedure.²¹⁰

Coronary Arterial Injury

The coronary arteries can be damaged by unintended or unrecognised entry while trying to cross the aortic valve, and myocardial infarction has been reported.^{84,213} A trans-septal approach will avoid these aortic complications. Delivery of energy on the atrioventricular ring may also cause heating of the wall of the coronary artery. Usually the rapid flow in the artery is able to dissipate heat and the wall is not permanently damaged, though mild stenoses have occurred in an experimental model.²¹⁴ Rarely, infarction has been recognised clinically.^{215,216}

Thromboembolism

When ablating on the left side of the heart, there is a risk of the thrombosis on the ablated area embolizing. Because of this, anticoagulants should always be used during the procedure and many centres give heparin overnight following the procedure. Some of these emboli may only occur in the days or weeks after the procedure. It is a routine, therefore, to give prophylactic aspirin for 4 to 6 weeks after a procedure on the systemic side of the circulation.^{213,217} There is very little data on which to base post-ablation anticoagulation, and thus a fair degree of variation in practise. On the right side of the heart, small pulmonary emboli are unlikely to be clinically apparent; in spite of this some also use heparin during the procedure and aspirin afterwards. This is mandatory when large areas are ablated, as when creating lines of block, or in patients with decreased flow, for example, after the Fontan operation.

Valvar Damage

Damage has been reported to the aortic valve and may be more common than after diagnostic catheterisation as the ablation catheter is stiffer than routine diagnostic catheters. A trans-septal approach is indicated if there is significant aortic valvar disease. The mitral valve can also be damaged during manipulation to place the ablation catheter under the valvar leaflets on the atrioventricular ring, and possibly by delivery of energy. In one echocardiographic study, mild new aortic regurgitation was reported in one-third of patients, and mitral regurgitation in one-eighth.²¹⁸ More commonly, mild valvar regurgitation occurs with a frequency of less than 2%.²¹⁹ If a patent oval foramen is present, then a trans-septal approach avoids problems of arterial access and reduces the incidence of possible valvar damage. Some have argued for routine trans-septal puncture in children to avoid the retrograde arterial approach.²²⁰ Trans-septal puncture carries risks of its own, and air embolism during changes of catheter has been reported.²²¹ There have been two non-randomised comparative studies of the retrograde and anterograde approaches, with a similar incidence of complications.²²² Lower fluoroscopy times, however, were reported with the trans-septal approach.²²³ In these studies, it was recognised that the two approaches could be complimentary, as failure by one route did not invalidate a successful procedure using the other route. Damage to the tricuspid valve is less common as it is rarely necessary to place the catheter below the valvar leaflets.

Cardiac Perforation and Tamponade

Tamponade due to perforation can present during or shortly after the procedure occurs.²²⁴ Perforation can occur during delivery of energy or manipulation of catheters. Excessive temperature and repeated applications at one site are recognised risk factors. Perforation is more common when ablating in the coronary sinus than around the atrioventricular groove. The stiffer ablation catheters themselves may be responsible for perforation during intracardiac manipulation in infants, thus producing a higher incidence of pericardial effusions.⁹³ Percutaneous drainage is usually sufficient, but open drainage with repair of the bleeding site is sometimes required. A slow leak into the pericardial space is also possible. Because of this, many centres routinely perform an echocardiogram the following day. Late

pericarditis and postpericardiotomy syndrome have also been reported.²²⁵

Exposure to Radiation and Non-fluoroscopic Mapping

Exposure during the earliest procedures was generally considerably longer than for routine diagnostic cardiac catheterisation, with times generally exceeding 1 hour, but not dissimilar to complex interventional catheterisation.²²⁶ Isolated reports of radiation skin injury were associated with these early procedures using older fluoroscopy equipment, and are still seen with particularly long procedures such as atrial fibrillation ablations.²²⁷ Early estimations were of a 0.1% per patient lifetime additional risk for a malignancy from fluoroscopy for 1 hour.²²⁸ This is to be viewed against a 20% risk per lifetime of an individual developing a malignancy naturally. Subsequent studies suggest this additional risk is closer to 0.03%.²²⁹ This small risk is outweighed by the benefits in avoiding a lifetime of medication, admissions to hospital, and the risks of antiarrhythmic surgery. In addition, it is highly cost effective.^{230–236} Using modern fluoroscopic systems with optimised fluoroscopy settings, beam collimation, pulsed fluoroscopy, and improved procedure times, the amount of radiation has been reduced. Most procedures now require less than 1 hour of fluoroscopy.⁸⁴ It may be better to abandon a procedure and return on another day with fresh and/or additional hands and minds and different equipment than persevering when the procedure is becoming increasingly difficult. Usage of electroanatomic mapping systems may assist in decreased amount of fluoroscopy required, and may also assist with creation of improved substrate maps.^{152,237–239}

Results of Radio-frequency Ablation

A number of single- and multi-centre studies have shown that the overall risk of radio-frequency ablation is low and the success rate is high. Currently, the success rate is more than 96% for nodal re-entry tachycardia, and more than 90% for accessory pathways. A learning curve of the order of 100 cases per institution has been noted. Centres that perform more procedures have a lower complication rate during shorter procedures, with shorter times required for fluoroscopy, and increased rates of success.^{205,240–243} This applies to radio-frequency ablation in both adults and children.²⁴⁴ Structural heart disease, a body weight of less than 15 kg, and the presence of multiple arrhythmic targets increase the risk of complications.

The multi-centre series (see Table 19-1) all have different criteria for inclusion and follow-up. In 1993, Hindricks reported the Multicentre European Radio-frequency Survey of almost 5000 adults treated up to 1992.¹³² Calkins and colleagues in 1998 reported on the ATAKR Multicentre Investigators Group of just over 1000 adults and children undergoing radio-frequency ablation of supraventricular arrhythmias including ablation of the atrioventricular node.¹³³ The Pediatric Electrophysiology Society of North America first reported in 1994 the acute results of ablation in patients aged less than 21 years. They included those with structural heart disease and those undergoing ablation for ventricular tachycardia.⁸⁵ A later follow-up of the patients with a structurally normal heart undergoing ablation for supraventricular

tachycardia was reported in 1997.⁸⁴ In these studies, the death rate was 0.1% to 0.3%, complete atrioventricular block occurred in 0.6% to 1% and pericardial tamponade or effusion in 0.7% to 2.5% (see Table 19-1). A prospective study of radio-frequency ablation of accessory pathways in children showed similar results, with overall acute success rates of 95.7%, highest for left free-wall pathways (97.8%) and slightly lower for right free-wall pathways at 90.8%.^{205,208}

Although the acute rates of success and complications have been well documented, with similar results for adults and children, there have been few studies of the longer-term outcome. Calkins et al reported recurrence rates of 5% after ablation for nodal re-entry, and 8% for accessory pathways. The median time to recurrence was 35 days. Studies from individual centres have reported recurrences after successful ablation of accessory pathways in about one-tenth of patients after follow-up of about 6 months.^{217,245–247} The majority occurred within the first few days of the procedure, and most patients underwent a successful second ablation. The most comprehensive follow-up study to date is from the Pediatric Electrophysiology Society.^{84,205} Surprisingly, given the impressive acute results, there was a significant incidence of late recurrent arrhythmias.

ELECTROPHYSIOLOGY LABORATORY

While it is possible to perform electrophysiologic studies in a simple X-ray theatre with a single-plane image intensifier, this is less than optimal. There are many advantages to performing studies in the diagnostic and interventional catheterisation laboratory, where facilities for sedation and anaesthesia, fluoroscopy, cineangiography, haemodynamic measurements and monitoring, electrical cardioversion, defibrillation and resuscitation are all readily available.

Positioning of catheters is guided by fluoroscopy, and biplane fluoroscopy in the oblique, frontal, and lateral projections enhances their optimal positioning. Some children, especially those with complex congenital heart disease, will also undergo diagnostic cardiac catheterisation and haemodynamic evaluation and/or catheter intervention during the same procedure. Transoesophageal echocardiography may be helpful in children with malformed hearts to guide the positioning of catheters or for transseptal puncture for access to the left atrium.²⁰⁶

Personnel

The staffing requirements for paediatric electrophysiology studies and radio-frequency ablation are similar to those required for diagnostic and interventional paediatric cardiac catheterisation (see Chapter 17). The operator and physiological measurement technician, however, will also require additional skills in planning, undertaking, and interpreting the diagnostic and therapeutic aspects of the electrophysiologic studies. In some laboratories, it is usual to have two physicians. One is then able to concentrate on the intracardiac signals and the other on manipulation of the catheter during ablative procedures. In some smaller centres, the team of physicians is composed of a dedicated electrophysiologist, usually with

predominantly adult experience, and a paediatric cardiologist. More commonly, a paediatric cardiologist who is also trained in electrophysiology undertakes the procedures. There are published guidelines for both personnel and equipment.^{204,248–250}

Indications for Electrophysiological Studies

Electrophysiological studies are not required in the management of all arrhythmias. When the nature of an arrhythmia is clear, symptoms are infrequent and transient, or medication is effective and well tolerated, invasive testing is not required. Some details as to appropriate indications are included with the guidelines (Table 19-2).²⁰⁴

Transoesophageal Electrophysiologic Studies

While the majority of studies are performed with intracardiac catheter electrodes, it is possible to perform limited studies of supraventricular arrhythmias via a transoesophageal electrode, which is in close proximity to the left atrium. These electrodes can be placed with minimal sedation even in small children and infants and are used for pacing and recording together with the surface electrocardiogram.^{251,252} Electrodes with tip deflectors allow pacing of the ventricle from within the stomach, although ventricular capture is inconsistent.²⁵³

Pacemaker Lead Studies

In the post-operative period, temporary epicardial leads attached to the atrium and ventricle can be used to stimulate and record for limited electrophysiological studies.²⁵⁴ In patients with certain permanent pacemakers, the pacemaker can be programmed to deliver stimuli for induction of arrhythmias and to display intracardiac electrograms, allowing limited non-invasive electrophysiological studies.

Equipment

Electrophysiologic Catheters

Although a limited electrophysiological study, and even catheter ablation, can be performed in some cases with a single bipolar electrode catheter that is moved to different sites in the heart, it is more usual to use between two and five multi-polar electrode catheters.²⁵⁵ The simplest electrode catheters have a single bipole with spacing of 0.5 to 1 cm between the poles to enable bipolar recording and pacing. Multi-polar catheters with 4, 6, 8 or 10 poles are used to record and display multiple simultaneous electrograms and allow pacing at different sites without constantly moving the catheter. These catheters are usually of 4 to 7 French size, but recently smaller catheters have become available. More specialised catheters pre-shaped into a ring with 20 poles for mapping around the tricuspid annulus (halo), and 64 or more pole basket or balloon mounted electrode arrays for high-density mapping inside a cardiac chamber, are occasionally used for complex cases. High-torque steerable, 4- to 10-pole catheters, of 0.018 to 0.25 inches, have also been designed for use inside the coronary arteries and peripheral coronary veins.

Stimulating and Recording

While a complete haemodynamic assessment is possible with one or two pressure amplifiers and recording channels and a single surface electrocardiographic lead, intracardiac

TABLE 19-2

INDICATIONS FOR RADIO-FREQUENCY CATHETER ABLATION (RFCA) PROCEDURES IN PEDIATRIC PATIENTS

Class I

1. WPW syndrome following an episode of aborted sudden cardiac death
2. The presence of WPW syndrome associated with syncope when there is a short pre-excited RR interval during atrial fibrillation (pre-excited RR interval, 250 ms) or the antegrade effective refractory period of the AP measured during programmed electrical stimulation is 250 msec
3. Chronic or recurrent SVT associated with ventricular dysfunction
4. Recurrent VT that is associated with haemodynamic compromise and is amenable to catheter ablation

Class IIa

1. Recurrent and/or symptomatic SVT refractory to conventional medical therapy and age >4 years
2. Impending congenital heart surgery when vascular or chamber access may be restricted following surgery
3. Chronic (occurring for 6–12 months following an initial event) or incessant SVT in the presence of normal ventricular function
4. Chronic or frequent recurrences of IART
5. Palpitations with inducible sustained SVT during electrophysiological testing

Class IIb

1. Asymptomatic pre-excitation (WPW pattern on ECG), age >5 years, with no recognized tachycardia, when the risks and benefits of the procedure and arrhythmia have been clearly explained
2. SVT, age >5 years, as an alternative to chronic antiarrhythmic therapy which has been effective in control of the arrhythmia
3. SVT, age <5 years (including infants) when antiarrhythmic medications, including sotalol and amiodarone, are not effective or associated with intolerable side effects
4. IART, one to three episodes per year, requiring medical intervention
5. AVN ablation and pacemaker insertion as an alternative therapy for recurrent or intractable IART
6. One episode of VT associated with haemodynamic compromise and which is amenable to catheter ablation

Class III

1. Asymptomatic WPW syndrome, age <5 years
2. SVT controlled with conventional antiarrhythmic medications, age <5 years
3. Nonsustained, paroxysmal VT which is not considered incessant (i.e., present on monitoring for hours at a time or on nearly all strips recorded during any 1-hour period of time) and where no concomitant ventricular dysfunction exists
4. Episodes of nonsustained SVT that do not require other therapy and/or are minimally symptomatic

AP, accessory pathway; AVN, atrioventricular node; ECG, electrocardiogram; IART, intra-atrial reentrant tachycardia; SVT, sustained ventricular tachycardia; VT, ventricular tachycardia; WPW, Wolff-Parkinson-White.

electrophysiology studies require considerably more sophisticated and expensive equipment. Usually there is the need for at least 3 (ideally 12) surface and 3 (ideally at least 4) intracardiac electrographic channels. The intracardiac signals are amplified and filtered to reduce noise and produce sharp deflections. Modern digital systems allow a full 12-lead surface electrocardiogram to be recorded, together with 16 or more intracardiac electrograms. The older approach of displaying the electrograms in real time on an oscilloscope, while simultaneously recording on a paper recorder and/or on magnetic tape, has been superseded by digital systems. These continuously store the

electrograms and allow recall of data when required, both intracardiac electrograms and 12-lead surface electrocardiograms, from any part of the study. A programmable electrophysiology stimulator capable of pacing at rates up to 6000 beats/min is used for pacing and delivering timed extrastimuli in order to induce, terminate and modify arrhythmias. It is interfaced with a junction box into which the catheter electrodes are connected so that recording and stimulation can be performed using each electrode.

PACING AND DEVICES

Paediatrics and the History of Pacing

The early history of pacing comprises a colourful collection of intriguing stories of bravery, ingenuity, and tenacity.²⁵⁶ Paediatric cardiologists should be aware that paediatric patients were at the forefront of these endeavours. The first pacemaker is attributed to Mark Lidwill, an Australian physician who demonstrated his device, which plugged in to a lighting point, in 1929 in Sydney.^{257,258} One pole was soaked in a strong salt solution and applied to the skin and the other was a needle plunged into the heart. It had been used at least on one occasion to successfully resuscitate a still-born babe in whom everything else had failed.

A new era for paediatric cardiology and the whole of medicine dawned in 1954 when C. Walton Lillehei first repaired a ventricular septal defect using cross-circulation.²⁵⁹ After this new surgery became established, post-operative complete heart block proved an important cause of mortality and in 1957 Lillehei first used direct myocardial stimulation from an external pacemaker powered by alternating current. After a power outage, Lillehei successfully pressed Earl Bakken to develop a portable transistorised battery-powered external pacemaker.²⁶⁰

In 1958 the first fully internal pacemaker was implanted by Swedish surgeon Ake Senning, a name well known to paediatric cardiologists.²⁶¹ The device failed within hours and was replaced by an identical model, which lasted 8 days. The 43-year-old patient had complete heart block and syncope and went on to have an additional 24 pacemakers over his lifetime. He survived a further 43 years.

Over the next 50 years, anti-bradycardia pacing became a standard therapy and pacemakers evolved well beyond

simple anti-bradycardia devices. Biventricular pacemakers have revolutionised the management of heart failure and implantable cardioverter-defibrillators are a cornerstone in the prevention of sudden cardiac death. Both are increasingly used in paediatric and congenital heart disease patients.

Anti-bradycardia Pacing

The decision to place a permanent pacemaker may not be straightforward, particularly in the case of paediatric and congenital heart disease populations. Evidenced-based guidelines for prescribing anti-bradycardia permanent pacemakers are published and updated in a carefully written and thoughtful document by the American College of Cardiology (available at: www.acc.org) in conjunction with the American Heart Association (www.americanheart.org) and the Heart Rhythm Society (www.hrsonline.org).⁴¹

Atrioventricular Block: Definitions

First-degree atrioventricular block is PR interval prolongation greater than the upper limit of normal for age. This can be gleaned from normative paediatric electrocardiographic data.²⁶²

The nomenclature of second-degree atrioventricular block has a fascinating history and often causes confusion.²⁶³ Mobitz type I second-degree atrioventricular block (Wenckebach) is usually associated with a narrow QRS complex and is generally considered benign. However, Mobitz type II second-degree block is not benign, as it is always anatomically infra-nodal and can be associated with less stable escape rhythms.

Type I block is classically characterised by progressive prolongation of the PR interval before a single non-conducted P-wave (Fig. 19-13). Type I block, however, is frequently atypical (especially in children) and can be diagnosed when the post-block PR interval is shorter than the pre-block PR interval (Fig. 19-14). In contrast, type II second-degree atrioventricular block is characterised by fixed PR intervals before and after blocked beats and is usually associated with a wide QRS complex (Fig. 19-15). When atrioventricular conduction occurs in a 2:1 pattern, block cannot be classified as type I or type II, although the width of the QRS may be suggestive (Fig. 19-16).²⁶⁴

Figure 19-13 Classic type I, or Wenckebach, atrioventricular block. With each beat, there is a progressive increase in the atrioventricular interval until there is failure of atrioventricular conduction.

Figure 19-14 Atypical type I atrioventricular block. There is baseline first-degree atrioventricular block in this example. The PR interval after failure of atrioventricular conduction is shorter than the pre-block PR interval.

Figure 19-15 Mobitz type II atrioventricular block. There is baseline first-degree atrioventricular block and a wide QRS complex. The PR interval after failure of atrioventricular conduction is exactly the same as the pre-block PR interval. This patient had syncope in the post-operative period after implantation of a prosthetic mitral valve. A pacemaker was subsequently placed.

Advanced second-degree atrioventricular block refers to non-conduction of two or more consecutive P waves but with some conducted beats, indicating some preservation of atrioventricular conduction. Third-degree atrioventricular block (complete heart block) is absence of atrioventricular conduction and characteristically has a regular escape rhythm (Fig. 19-17).

Symptomatic Bradycardia: Definition

Sinus node dysfunction is increasingly recognised in paediatric patients, especially in those who have had surgery for congenital heart disease. It is frequently asymptomatic and in a large percentage of cases does not require pacing. Sinus node dysfunction may include sinus bradycardia, sinus pause, or sinus arrest, as well as sino-atrial block. Each of these bradycardias may occur as part of bradycardia-tachycardia syndrome.²⁶⁵

With respect to bradycardia the primary criterion for prescribing an anti-bradycardia pacemaker is the concurrent observation of symptoms. The clinical significance of bradycardia is age dependent. For example, a resting heart rate of 45 may be a normal finding in a fit adolescent, but in a neonate represents a profound bradycardia. Symptomatic bradycardia is defined as a documented bradyarrhythmia that is directly responsible for the clinical manifestations of syncope or near syncope, transient dizziness or light-headedness, or confusional states resulting from

cerebral hypoperfusion. Fatigue, exercise intolerance, and congestive cardiac failure may also result from bradycardia and these may occur at rest and/or with exertion.⁴¹

The following guidelines for the Holter diagnosis of sinus bradycardia have been proposed based on available normative data but unfortunately most of the data does not distinguish between the asleep and awake state²⁶⁵: neonates and infants: <60 beats per minute sleeping and <80 beats per minute during waking hours; children aged 1–6 years: <60 beats per minute; children aged 7–11 years: <45 beats per minute; adolescents and young adults: <40 beats per minute; trained athletes: <30 beats per minute.

Definite correlation of symptoms with bradyarrhythmia is required prior to determining the need for permanent pacing. Caution should be exercised not to confuse physiologic sinus bradycardia (as may occur in trained athletes) with pathological bradyarrhythmias. Alternative causes need to be considered and excluded as causative of the symptoms or bradycardia. These include anaemia, iron deficiency, hypothyroidism, space-occupying lesions of the central nervous system, Arnold-Chiari malformations, seizures, breath holding, apnoea, and other neurally-mediated mechanisms. On occasion, symptoms may only become apparent in retrospect after anti-bradycardia pacing.

In patients with congenital heart disease, abnormal physiology and ventricular performance can result in symptomatic bradycardia at rates that would not be symptomatic in those with more normal physiology. In these patients

Figure 19-16 The tracing shows 2:1 atrioventricular block. This block cannot be classified as type I or type II, but the wide QRS is suggestive of infra-nodal block. Each P-wave is marked with a P; every second P is fused with the end of the T wave.

Figure 19-17 Complete atrioventricular block. The atrial rate is 135 beats per minute. The ventricular rate is 50 beats per minute. The P waves bear no relationship to the QRS complexes, which are regular. The QRS complex is wide, which in this patient with congenital complete heart block is an indication for anti-bradycardia pacing.

a lower threshold for pacing is based on the correlation of symptoms with relative bradycardia.

Implantation Guidelines

Pacemaker implantation guidelines for children, adolescents, and patients, with congenital heart disease are outlined and specific situations are discussed below.⁴¹ Sometimes it is helpful to review adult parts of the document. With each new set of guidelines there has been a progressive trend towards less restrictive indications. Frequently individual judgements are required within the context of the document.²⁶⁶

Class I (there is evidence and/or general agreement that pacing is beneficial, useful, and effective)

1. Advanced second- or third-degree atrioventricular block associated with symptomatic bradycardia, ventricular dysfunction, or low cardiac output.
2. Sinus node dysfunction with correlation of symptoms during age-inappropriate bradycardia. The definition of bradycardia varies with the patient's age and expected heart rate.
3. Post-operative advanced second- or third-degree atrioventricular block that is not expected to resolve or persists at least 7 days after cardiac surgery.
4. Congenital third-degree atrioventricular block with a wide QRS escape rhythm, complex ventricular ectopy, or ventricular dysfunction.
5. Congenital third-degree atrioventricular block in the infant with a ventricular rate less than 50–55 beats per minute or with congenital heart disease and a ventricular rate less than 70 beats per minute.
6. Sustained pause-dependent ventricular tachycardia, with or without prolonged QT, in which the efficacy of pacing is thoroughly documented.

Class II (conditions for which there is conflicting evidence and/or a divergence of opinion)

Class IIa (weight of evidence favours pacing)

1. Bradycardia-tachycardia syndrome with the need for long-term antiarrhythmic treatment other than digitalis.
2. Congenital third-degree atrioventricular block beyond the first year of life with an average heart rate less than 50 beats per minute, abrupt pauses in ventricular rate that are two or three times the basic cycle length, or associated with symptoms due to chronotropic incompetence.
3. Long-QT syndrome with 2:1 atrioventricular or third-degree atrioventricular block.
4. Asymptomatic sinus bradycardia in the child with complex congenital heart disease with resting heart rate less than 40 beats per minute or pauses in ventricular rate more than 3 seconds.
5. Patients with congenital heart disease and impaired haemodynamics due to sinus bradycardia or loss of atrioventricular synchrony.

Class IIb (evidence for pacing is less well established)

1. Transient post-operative third-degree atrioventricular block that reverts to sinus rhythm with residual bifascicular block.

2. Congenital third-degree atrioventricular block in the asymptomatic infant, child, adolescent, or young adult with an acceptable rate, narrow QRS complex, and normal ventricular function.
3. Asymptomatic sinus bradycardia in the adolescent with congenital heart disease with resting heart rate less than 40 beats per minute or pauses in ventricular rate more than 3 seconds.
4. Neuromuscular diseases with any degree of atrioventricular block (including first-degree atrioventricular block), with or without symptoms, because there may be unpredictable progression of atrioventricular conduction disease.

Class III (pacing not indicated)

1. Transient post-operative atrioventricular block with return of normal atrioventricular conduction.
2. Asymptomatic post-operative bifascicular block with or without first-degree atrioventricular block.
3. Asymptomatic type I second-degree atrioventricular block.
4. Asymptomatic sinus bradycardia in the adolescent with longest RR interval less than 3 seconds and minimum heart rate more than 40 beats per minute.

Congenital Complete Atrioventricular Block

Congenital complete atrioventricular block is strongly associated with maternal anti-Ro and anti-La antibodies and occurs in up to 5% of fetuses whose mothers have these antibodies. The pathogenesis of block in this situation is complicated and incompletely understood.²⁶⁷ Interestingly in twin pregnancies only one twin may be afflicted.²⁶⁸ Diagnosis can be made antenatally and demonstration of degrees of block less than third degree remains a controversial indication for treatment with steroids to potentially avert progression (see Chapter 12). Other aetiologies include inherited conduction system diseases with diverse genetic bases.²⁶⁹

The primary reason for anti-bradycardia pacing for congenital complete heart block is to prevent syncope and sudden death.²⁷⁰ In addition to alleviating symptoms, anti-bradycardia pacing may prevent ventricular dysfunction and associated mitral regurgitation.
